11 **ABSTRACT**

12 **Background:** During the first wave of COVID-19 it was hypothesized that COVID-19 is subject to multi-wave
13 seasonality, similar to Influenza-Like Illnesses since time immemorial. One year into the pandemic, we aimed to
14 test the seasonality hypothesis for COVID-19.

15 **Methods:** We calculated the average annual time-series for Influenza-Like Illnesses based on incidence data
16 from 2016 till 2019 in the Netherlands, and compared these with two COVID-19 time-series during 2020/2021
17 for the Netherlands. We plotted the time-series on a standardized logarithmic infection scale. Finally, we
18 calculated correlation coefficients and used univariate regression analysis to estimate the strength of the
19 association between the time-series of COVID-19 and Influenza-Like Illnesses.

20 **Results:** The time-series for COVID-19 and Influenza-Like Illnesses were strongly and highly significantly
21 correlated. The COVID-19 peaks were all during flu season, and lows were all in the opposing period. Finally,
22 COVID-19 meets the multi-wave characteristics of earlier flu-like pandemics, namely a short first wave at the
23 tail-end of a flu season, and a longer and more intense second wave during the subsequent flu season.

NOTE: This preprint reports new research that has not been certified by peer review and should not be used to guide clinical practice.

24 **Conclusions:** We conclude that seasonal patterns of COVID-19 incidence and Influenza-Like Illnesses incidence
25 are highly similar, in a country in the temperate climate zone, such as the Netherlands. Further, the COVID-19
26 pandemic satisfies the criteria of earlier respiratory pandemics, namely a first wave that is short-lived at the tail-
27 end of flu season, and a second wave that is longer and more severe.

28 This seems to imply that the same factors that are driving the seasonality of Influenza-Like Illnesses are causing
29 COVID-19 seasonality as well, such as solar radiation (UV), temperature, relative humidity, and subsequently
30 seasonal allergens and allergies.

31 **KEYWORDS**

32 COVID-19 incidence, seasonality, Influenza-Like Illnesses, respiratory viruses

33 **HIGHLIGHTS**

- 34 • Time-series analysis shows that COVID-19 and historic of Influenza-Like illnesses have highly similar
35 seasonal patterns in the Netherlands.
- 36 • COVID-19 satisfies the criteria of earlier flu-like pandemics, namely a short cycle at the end of flu
37 season, and a longer, more intense cycle during the subsequent flu season.
- 38 • The implication is that the seasonal factors driving flu season, are also responsible for COVID-19
39 seasonality.
- 40 • We developed and applied a new method to determine seasonality, encompassing comparative time-
41 series analysis, a standardized logarithmic infection scale, and qualitative seasonality criteria.

42

43 **1. INTRODUCTION**

44 During the first wave of COVID-19 it was hypothesized that COVID-19 is subject to multi-wave seasonality [1,
45 2], comparable to other respiratory viral infections and pandemics since time immemorial [3, 4]. It is observed
46 that the COVID-19 community outbreaks have a similar pattern as other seasonal respiratory viruses [5, 6, 7].
47 Already during the first COVID-19 cycle the data suggested seasonality, comparable to the seasonality of
48 Influenza-Like Illnesses (ILI), although the time-series were typically too short for definitive conclusions [8].
49 Currently, we are one year into the COVID-19 pandemic, and we can witness in the temperate climate zone in

50 the Northern Hemisphere, a second wave that appears to rise and peak during the boundaries of a typical flu
51 season, as the first cycle before.

52 Until now, it is not yet confirmed that COVID-19 behaves as seasonal as ILI. Therefore, we aim to test our
53 hypothesis that COVID-19 has a similar seasonal pattern as ILI in a country in the temperate climate zone as the
54 Netherlands. To test our hypothesis, we performed time-series analysis to compare the COVID-19 cycles with
55 the multi-wave seasonality patterns of flu-like illnesses. In addition, we analyzed to what degree the COVID-19
56 pandemic fulfills the qualitative characteristics of earlier flu-like pandemics and seasonality as mentioned by Fox
57 et al. Particularly, a short first wave at the tail end of a flu season, and a more severe second wave during the
58 following flu season. We further expect peaks to occur within the seasonal boundaries between week 33 (± 2
59 weeks) and week 10 (± 5 weeks), and the nadir in the opposing period which coincides with the allergy season
60 [8, 9].

61 The main objective of this study is to provide a predictive model for subsequent COVID-19 seasonal cycles.

62

63 **2. METHODS**

64 **2.1 Data**

65 *Incidence of Influenza-Like Illnesses*

66 We used data from the Dutch State Institute for Public Health (RIVM) gathered by the Dutch institute for
67 research of the health care (Nivel) about weekly flu-like incidence (WHO code “ILI” - Influenza-Like Illnesses).
68 ILI is defined by the WHO as a combination of a measured fever of $\geq 38^{\circ}\text{C}$, and a cough, with an onset within
69 the last 10 days. The Dutch ILI reports are gathered from primary medical care. Primary medical care is the first-
70 line healthcare provided by general practitioners to their registered patients as typical in the Netherlands, with its
71 current population of 17.4 million. The reports are confirmed by a positive RIVM laboratory test for ILI [10].

72 The flu-like incidence metric is a weekly average based on a representative group of 40 primary care units. It is
73 calculated using the number of influenza-like reports per primary care unit divided by the number of patients
74 registered at that unit. This is then averaged for all primary care units in the Netherlands, extrapolated to the
75 entire population, and reported as the ‘ILI incidence per 100,000 citizens in the Netherlands’. The datasets run
76 from week 1 of 2016 up to week 52 of 2019 to preclude the COVID-19 pandemic and avoid the impact of

77 lockdowns and other COVID-19 related restrictions on ILI in the 2020/2021 season. We used these data to
78 calculate the average ILI incidence per week ($n = 52$) as our baseline times series.

79 *COVID-19 incidence*

80 To calculate the COVID-19 incidence, we used the RIVM data set which reports the daily COVID-19 incidence
81 per municipality [11]. The incidence per municipality is based on positive COVID-19 tests that are reported via
82 the local municipality health services (Gemeentelijke Gezondheidsdienst; GGD), that are under the control of the
83 RIVM. We aggregated the crude number into a weekly COVID-19 incidence for the Netherlands per 100,000
84 citizens, to create a metric on the same scale as the standard ILI metric. We calculated the values from week 13,
85 2020, the peak of the short first COVID-19 cycle in the Netherlands, till week 5, 2021 ($n = 45$). We assume that
86 the cycles themselves are sufficiently representative for time-series analysis, even though the COVID-19
87 incidence during the first cycle is most likely underestimated compared to incidence during the second cycle, due
88 to test bias. With test bias, we mean that both the method of testing and the test capacity, altered during the
89 development of the COVID-19 pandemic. Especially, at the start of the pandemic, there was a shortage of test
90 capacity in the Netherlands. The capacity shortage had considerably improved since the end of March, i.e., week
91 13 of 2020, but only in the first months of 2021 reached sufficient levels.

92 Therefore, as a sensitivity analysis, we used a second dataset from RIVM, which is based on data from the Dutch
93 national intensive care evaluation foundation [12]. Based on hospital admissions, the RIVM estimated the
94 COVID-19 incidence in the Netherlands, assuming a delay of at least 7 days between the COVID-19 infection
95 and hospital admission. This dataset provides the average COVID-19 incidence per day with a 95% confidence
96 interval (95% CI). Again, we calculated the average weekly COVID-19 incidence for the Netherlands per
97 100,000 citizens, to create a metric on the same scale as the standard ILI metric.

98

99 **2.2 Statistical analysis**

100 Variables are presented with their means (M) and standard deviations (SD). We calculated correlation
101 coefficients to test the hypotheses and to assess the strength and direction of relationships.

102

103 Because the time-series were nonlinear and somewhat skewed, we used the \log_{10} transformation before applying
104 linear regression and calculating correlation coefficients, which requires a normal distribution. After the \log_{10}
105 transformation, we multiplied the data with factor 2 to create an intuitive scale from 0 to 10 for ILI and COVID-

106 19, which is comparable to the 1 to 12 logarithmic Richter scale for earthquakes [13]. The logarithmic scale we
107 elaborated is rational and plots exponential characteristics on a linear infections scale [14]. We added descriptive
108 labels to each scale as an aid for qualitative interpretation in intuitive, layman terms (see Table 1). Other
109 advantages are that it makes a comparison between different epidemics or pandemics, and thus external
110 validation, easier. Finally, it enlarges the critical early stages of an epidemic, and it reduces the extreme peaks
111 and resulting test bias because of test capacity overloads.

112

113 Linear regression (F-test) on the ILI and COVID-19 time-series is performed as a sensitivity analysis and used
114 *descriptively* to determine the strength of the relationship between the COVID-19 and ILI time-series. More in
115 detail to determine the equation using estimates and intercept values, probability, significance level, F-value, and
116 the Multiple R squared correlation to understand the predictive power of the respective relation. Standard
117 deviations and errors and degrees of freedom (DF) were used as input for calculating the 95% probability
118 interval.

119 We have reported the results in APA style, adapted to journal requirements.

120 Correlations are calculated manually in Excel, and for linear regression Graphpad 2021 is used (which we
121 benchmarked on R version 3.5).

122

123 **3. RESULTS**

124 **3.1 Data analysis**

125 The means and standard deviations of the dataset are summarized in Table 2.

126 Figure 1 shows a short first COVID-19 wave at the tail end of the 2019/2020 flu season, and a more severe
127 second wave during the 2020/2021 flu season in terms of total incidence. The peaks are all within the seasonal
128 boundaries between week 33 (± 2 weeks) and week 10 (± 5 weeks), and the nadirs in the opposing period. The
129 hospitalizations-based estimates for COVID-19 incidence provide likely a more realistic picture of especially,
130 the first wave, given test bias. However, on a logarithmic scale, the first COVID-19 wave appears more visually
131 comparable in both time-series.

132 On our logarithmic infection scale (Fig. 2), the estimated COVID-19 incidence tops around 6 (severe epidemic
133 level), and the nadir bottoms out around 3 (severe outbreak level). Interestingly, on this scale, it becomes visible
134 that COVID-19 incidence starts to rise slightly earlier than what is usual for ILI (week 33 ± 2 weeks).

135

136 **3.2 Statistical outcomes**

137 The COVID-19 time-series strongly and highly significantly correlates with the ILI time-series $r(45) = 0.75$ ($p <$
138 0.00001). The hospitalizations-based, COVID-19 time-series, providing estimates that control for test bias,
139 correlated even somewhat stronger, ($r(45) = 0.798$, $p < 0.00001$), and as significantly (Fig. 3). The correlations
140 (95% CI) of the estimated COVID-19 incidence time-series are almost equal, respectively $r(45) = 0.788$, $p <$
141 0.00001 and $r(45) = 0.803$, $p < 0.00001$. Therefore, we conclude that the COVID-19 time-series have a similar
142 wave pattern to the ILI time-series, which have long been established as being seasonal. Furthermore, the
143 COVID-19 peaks, similar to ILI peaks, all occur during flu season, i.e., between week $33 (\pm 2$ weeks) and week
144 $10 (\pm 5$ weeks). In addition, the COVID-19 nadirs, similar to ILI nadirs, occur all in the opposing allergy season.

145 As a second sensitivity analysis, we performed univariate regression analyses between both the COVID-19 time-
146 series, and the average ILI time-series. The outcomes were again highly significant: respectively $F(1, 43) =$
147 61.45 , $p < 0.0001$, and $F(1, 43) = 81.18$, $p < 0.0001$ and the correlations (r^2) are moderate to strong (see Table
148 3).

149

150 **4. DISCUSSION**

151 Given the strong, and highly significant, correlations between the ILI and COVID-19 time-series, we conclude
152 that COVID-19 incidence follows a seasonal pattern that is similar to ILI incidence in a country in the temperate
153 climate zone, such as the Netherlands. Moreover, the COVID-19 peaks are all during flu season, and lows are all
154 in the opposing period as expected. Furthermore, the COVID-19 time-series is in accordance with the two
155 characteristics of earlier pandemics [4], namely a short first wave at the tail-end of a flu season, and a longer and
156 more intense second wave during the subsequent flu season. This implies that the subsequent endings and starts
157 of each following wave are more or less predictable. If the history of pandemics is followed, the third COVID-19
158 wave would be less severe than the second one. Though nowadays vaccination will be a more important factor in
159 determining the amplitude of the subsequent waves.

160 Interestingly, all over Europe, the COVID-19 cycles were all more or less in sync with the Dutch COVID-19
161 cycle [15], and thus ILI seasonality, independent of the start of the first cycle, the severity of lockdown measures
162 taken, and given that herd immunity is not yet reached. The seasonality pattern of COVID-19 appears to be
163 influenced though not caused by social distancing and lockdown measures as these measures were mainly anti-
164 cyclical and following the trend. They were increasingly applied to flatten the curve after COVID-19 incidence
165 increases, gradually lifted after the sharper than expected COVID-19 downcycles in Spring and Summer, and
166 only re-applied after the second wave seriously kicked in, during Autumn and Winter. It is beyond our research
167 to quantify the considerable impact of lockdown and social distancing measures, although it might explain that
168 COVID-19 incidence on the logarithmic scale (see Fig. 2) starts to rise slightly earlier than what is usual for ILI
169 (week 33 ± 2 weeks) as social distancing and lockdown measures were increasingly relaxed and ignored in this
170 period.

171 What environmental factors have caused COVID-19 seasonality? We have analyzed before that the likely
172 inhibiting factor causing ILI seasonality, before or during COVID-19, are seasonal allergens (i.e. pollens) and
173 seasonal allergies [8, 9], given that meteorological factors alone are not sufficient to explain the seasonality of
174 ILI [16] or COVID-19 [17]. We used data from a pollen station in Helmond, the Netherlands (latitude 51.48167,
175 longitude 5.66111). On the other hand, we identified solar radiation (UV) as an ILI/COVID-19 co-inhibitor, and
176 it is well-established that dry, warm, and sunny weather stimulates the maturation and dispersion of pollens.

177 The inverse seasonality of seasonal allergens and ILI including COVID-19 is independently confirmed by a
178 recent Chicago (latitude 41.85003, longitude -87.65005) study that covered not only pollens but also mold
179 spores [18]. These findings seemingly contradict an early international study of pollen and COVID-19 [19],
180 which suffers from the same issues as many other early environmental COVID-19 studies: both sub-seasonal
181 bias and COVID-19 test bias. Sub-seasonal bias, means here that a too limited time-series sample is used,
182 namely from January till the beginning of April 2020, which coincides with only a small part of the early
183 upswing in COVID-19 incidence in most countries, and mainly the upswing of allergens in the northern
184 hemisphere. Further, the assumed lag of precisely 4 days seems to be problematic as people typically do not get
185 immediately tested when they show the first COVID-19 symptoms. Additionally, conflicting local outcomes
186 were selectively removed from the study. And, finally, in this short time window used it might have been better
187 to correlate with a sound R_0 estimate, correcting for test bias, than only the raw incidence figures, to be able to
188 discern deceleration/acceleration effects during the upswing.

189 We think that studies that are more geographically focused, and work with longer time-series, are in the current

190 phase more meaningful for analyzing the pollen effect on COVID-19 incidence while controlling for deviations
191 in other local circumstances. Therefore, we would expect that, ceteris paribus, the results of our COVID-19 and
192 ILI pattern comparison in this study, implies that a 12-month time-series analysis of the R_0 of COVID-19 and
193 pollen concentrations would falsify the outcomes of this international study, at least for the Netherlands.

194 Although the allergenic role of pollen is widely known [20, 21, 22], its role in immuno-activation [23] is
195 highlighted only recently. Owing to extensive COVID-19 research, pathophysiological explanations have been
196 established upon the observation that allergic diseases are associated with lower rates of COVID-19
197 hospitalizations [24, 25]. An explanation is provided by Jackson et al. [26], who proved that allergic sensitization
198 and allergen natural exposure are inversely related to membrane-bound angiotensin-converting enzyme 2 (ACE-
199 2) expression, whereby it is known that severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) uses the
200 ACE-2 receptor to gain cell entry, leading to COVID-19 [27]. Additionally, it is hypothesized that seasonal
201 allergens, especially pollen and mold spores, compete with flu-like viruses for access to another receptor, the
202 Toll-Like Receptor 4 (TLR4) [18], in an attempt to explain the inverse seasonality of seasonal allergens and flu-
203 like illnesses, both for people with and without allergic diseases.

204 Another explanation is based on the higher eosinophil count in children with allergic diseases than COVID-19
205 patients [28], whereby eosinophils are known to clear viral load, and contribute to the recovery from viral
206 infections, supposedly including COVID-19 [29].

207 Furthermore, histamine and IgE serum levels are elevated in allergic rhinitis and other atopy patients which
208 downplay other anti-viral responses (plasmacytoid dendritic cells and interferon- α) but might thus prevent the
209 cytokine storm and hyper-inflammation that typically mark severe outcomes of respiratory diseases, including
210 COVID-19 [30] and influenza. And, it is discussed that homologies between SARS-CoV-2 and allergen proteins,
211 especially from the spores of molds (*Aspergillus fumigatus*) and the pollen of grasses (*Phleum pratense*) may
212 direct T cell-mediated heterologous immune responses [31] which might help explain the protective effect of
213 allergies against COVID-19 hospitalization as well.

214 Finally, it is well-established that pollens have anti-viral phytochemicals [32], which is also the case for mold
215 spores [33]. Although the nature of the bioaerosol interaction with COVID-19 viruses is not well investigated yet
216 it can be imagined that pollens and spores might compete with viral bioaerosol in the environment.

217 *Methodological concerns*

218 Test bias, especially for new viruses such as COVID-19, is a major methodological challenge. The approach to
219 use more reliable metrics like the number of hospitalizations to generate an alternative incidence metric appears
220 to be a good method to control for test bias. We could observe that the test bias slightly reduced the strength of
221 correlations, which in our case did not affect the conclusions. During 2020-2021, the test capacity was scaled up
222 significantly and sufficiently, which reduced the test bias concern over time.

223 Another sound approach used seems to be excess mortality estimates. In this study, we decided not to use the
224 latter, as there are other known factors than seasonal viruses that cause excess mortality, such as the heatwave
225 during the Summer of 2020. Thus, using excess mortality would just introduce a measurement validity concern.
226

227 **5. CONCLUSION**

228 The COVID-19 pandemic in the Netherlands is till now as seasonal as flu-like illnesses given the highly
229 significant and strong correlations between both time-series. But, also given that COVID-19 waves till now rise
230 between the temporal boundaries (week 10 \pm 5 weeks and week 33 \pm 2 weeks) of the typical flu-like season in
231 The Netherlands, and go down in the opposing periods. Further, the COVID-19 pandemic satisfies the
232 qualitative criteria of earlier respiratory pandemics since 1889: the first wave is short-lived at the tail-end of flu
233 season, the second wave is longer and more severe, peaks fall within the boundaries of flu-like season, and the
234 lows are during the boundaries of the opposing season.

235 This logically seems to imply that, *ceteris paribus*, the same factors that are driving the seasonality of Influenza-
236 Like Illnesses are causing COVID-19 seasonality, such as solar radiation (UV), temperature, relative humidity,
237 and subsequently seasonal allergens and allergies.

328 FIGURES AND TABLES

329

Table 1: Logarithmic Infection Scale

$2^* \text{LOG}_{10}(\text{Incidence}/100\text{K})$	Incidence	Incidence (% of	Description
	(/100K citizens)	population	
		infected)	

0	1	0.001%	Isolated incidents
1	3	0.003%	Mild outbreak
2	10	0.01%	Moderate outbreak
3	30	0.03%	Severe outbreak
3.5	58	0.06%	Epidemic threshold (example)
4	100	0.1%	Mild Epidemic
5	300	0.3%	Moderate epidemic
6	1000	1%	Severe epidemic
7	3000	3%	Very severe epidemic
8	10000	10%	Public health catastrophe
9	30000	30%	Severe public health catastrophe
10	100000	100%	Total public health catastrophe

330 *Table 1: Logarithmic scale [1, 10] of Influenza-Like Illnesses or COVID-19 (or other) incidence because of the*
 331 *exponential nature of epidemics, with proposed qualitative descriptions for convenience.*

332 **Table 2: overview means (M) and standard deviations (SDs)**

Variable	2*Log ₁₀ transformed			
	Mean	SD	Mean	SD
Average incidence ILI/100K 2016 till 2019	46	36	3.07	0.69
COVID-19 incidence/100K	126	141	3.34	1.43
COVID-19 incidence/100K estimate based on hospitalizations (average)	415	337	4.69	1.17
COVID-19 incidence/100K estimate based on hospitalizations (lower 95% CI)	300	247	4.38	1.22
COVID-19 incidence/100K estimate based on hospitalizations (upper 95% CI)	531	426	4.93	1.14

333 *Table 2: Overview of means (M) and standard deviations (SD) per variable in the ILI (Influenza-Like Illnesses)*
 334 *and COVID-19 datasets, including 2*Log₁₀ transformed data.*

335
 336 **Figure 1.**

337

338 *Fig. 1. Historical ILI (Influenza-Like Illnesses) incidence (2016 till 2019) versus COVID-19 incidence per 100K*
339 *citizens during the 2020/2021 season. Peaks are all during flu season, and lows during the opposite season. The*
340 *shaded periods are the typical period in which seasonal switching occurs.*

341

Figure 2.

342

343

344 *Fig. 2. Historical ILI (Influenza-Like Illnesses) incidence (2016 till 2019) versus COVID-19 incidence per 100K*
 345 *citizens (2020/2021) on the 1 to 10 logarithmic scale. This figure visualizes the similarity of the COVID-19 time-*
 346 *series based on hospitalizations with the historic ILI time-series. The shaded areas are the typical seasonal*
 347 *switching periods.*

348

349

Figure 3.

350

351 *Fig. 3. Scatter diagram showing the relation between the estimated COVID-19 incidence/100K citizens and the*
 352 *seasonal, average incidence of Influenza-Like Illnesses (ILI)/100K citizens in the Netherlands of the preceding 4*
 353 *years.*

354

355

Table 3: outcomes linear regression

356

357

2*LOG₁₀(ILI/100K)	Estimate	CI 95%	Intercept	R²	F-stat on DF	P<
2*LOG₁₀(COVID-19 incidence/100K)	1.81	1.34 to 2.28	1.95	0.59	61.45 (1, 43)	0.0001

2*LOG₁₀(COVID-19							
incidence/100K) estimate	1.54	1.20 to 1.89	0.19	0.65	81.18 (1, 43)	0.0001	
based on hospitalizations							

358

359 *Table 3: Univariate regression analyses of the average Influenza-Like Illnesses (ILI) incidence/100K citizens on*
360 *both time-series for COVID-19 incidence/100K citizens, whereby each time-series is 2*LOG₁₀ transformed to*
361 *compensate for non-linearity, and thus plotted on a 1 to 10 rational scale.*

387 **Linear Regression**

388

Best-fit values	
Slope	1.810 ± 0.2309
Y-intercept	-1.946 ± 0.6886
X-intercept	1.075
1/Slope	0.5524
95% Confidence Intervals	
Slope	1.344 to 2.276
Y-intercept	-3.335 to -0.5566
X-intercept	0.4106 to 1.477
Goodness of Fit	
R square	0.5883
Sy.x	0.9350
Is slope significantly non-zero?	
F	61.45
DFn,DFd	1,43
P Value	< 0.0001
Deviation from horizontal?	Significant
Data	
Number of XY pairs	45
Equation	$Y = 1.810 * X - 1.946$

389

390

Best-fit values	
Slope	1.544 ± 0.1714
Y-intercept	0.1862 ± 0.5111
X-intercept	-0.1206
1/Slope	0.6475
95% Confidence Intervals	
Slope	1.198 to 1.890
Y-intercept	-0.8450 to 1.217
X-intercept	-1.011 to 0.4491
Goodness of Fit	
R square	0.6537
Sy.x	0.6939
Is slope significantly non-zero?	
F	81.18
DFn,DFd	1,43
P Value	< 0.0001
Deviation from horizontal?	Significant
Data	
Number of XY pairs	45
Equation	$Y = 1.544 * X + 0.1862$
