Abstract

Background: Chest pain is the second leading reason for emergency department (ED) visits and is commonly identified as a leading driver of low-value health care. Accurate identification of patients at low risk of major adverse cardiac events (MACE) is important to improve resource allocation and reduce over-treatment.

Objectives: We sought to assess machine learning (ML) methods and electronic health record (EHR) covariate collection for MACE prediction. We aimed to maximize the pool of low-risk patients that are accurately predicted to have less than 0.5% MACE risk and may be eligible for reduced testing.

Population Studied: 116,764 adult patients presenting with chest pain in the ED and evaluated for potential acute coronary syndrome (ACS). 60-day MACE rate was 1.9%.

Methods: We evaluated ML algorithms (lasso, splines, random forest, extreme gradient boosting, Bayesian additive regression trees) and SuperLearner stacked ensembling. We tuned ML hyperparameters through nested ensembling, and imputed missing values with generalized low-rank models (GLRM). We benchmarked performance to key biomarkers, validated clinical risk scores, decision trees, and logistic regression. We explained the models through variable importance ranking and accumulated local effect visualization.

Results: The best discrimination (area under the precision-recall [PR-AUC] and receiver operating characteristic [ROC-AUC] curves) was provided by SuperLearner ensembling (0.148, 0.867), followed by random forest (0.146, 0.862). Logistic regression (0.120, 0.842) and decision trees (0.094, 0.805) exhibited worse discrimination, as did risk scores [HEART (0.064, 0.765), EDACS (0.046, 0.733)] and biomarkers [serum troponin level (0.064, 0.708), electrocardiography (0.047, 0.686)]. The ensemble's risk estimates were miscalibrated by 0.2 percentage points. The ensemble accurately identified 50% of patients to be below a 0.5% 60-day MACE risk threshold. The most important predictors were age, peak troponin, HEART score, EDACS score, and electrocardiogram. GLRM imputation achieved 90% reduction in root mean-squared error compared to median-mode imputation.

Conclusion: Use of ML algorithms, combined with broad predictor sets, improved MACE risk prediction compared to simpler alternatives, while providing calibrated

predictions and interpretability. Standard risk scores may neglect important health information available in other characteristics and combined in nuanced ways via ML.

Keywords: chest pain, clinical predictive model, prognostic modeling, interpretable machine learning, ensemble learning, variable importance, accumulated local effects, generalized low-rank models

> The omission of prediction from the major goals of basic medical science has impoverished the intellectual content of clinical work, since a modern clinician's main challenge in the care of patients is to make predictions.

1 Introduction

Chest pain is the second leading reason for emergency department visits (Rui et al. 2016) and is commonly identified as a leading driver of low-value health care. Workup protocols in patients with chest pain are designed to diagnose the potential for major adverse cardiac events (MACE). Missed diagnoses of MACE can be cause for medico-legal action, which may encourage conservative testing without health benefit. Accurate identification of patients at low risk of MACE is important to improve resource allocation and reduce overtreatment (Amsterdam et al. 2010). Risk scores aim to identify patients eligible for early discharge, avoiding additional stress testing and cardiac imaging that is unlikely to be of benefit (Greenslade et al. 2018). The primary biomarkers used for initial triage are elevated cardiac troponin, a sensitive marker of cardiac injury measured serially, and repeated electrocardiograms.

Previous work has focused on the development and validation of additive risk scores as decision aids for risk stratification. Such risk scores examine a small number of biomarkers and demographics, summarize those predictors into qualitative levels, and use a weighted sum to allocate patients into risk categories. Standard risk scores are HEART (History, ECG, Age, Risk factors and Troponin) and EDACS (Emergency Department Assessment of Chest Pain Score - Than, Flaws, et al. 2014). HEART is most commonly used in North America, although EDACS has similar performance characteristics (Mark et al. 2018). Effective risk scores will stratify patients across risk levels such that the qualitative "low risk" group will have sufficiently low risk of short-term MACE that those patients can be discharged without additional workup. An ineffective or ill-calibrated risk score would underestimate the risk in the "low risk" group and lead to an overly optimistic early discharge policy that results in increased future MACE. But given multiple risk scores that are well-calibrated, scores with improved discrimination could theoretically result in a larger percentage of low-risk patients.

1.1 Background and Objectives

It remains debated whether machine learning methods can exhibit statistically and substantively significant benefits for risk prediction compared to logistic regression, decision trees, or additive risk scores (Goldstein, Navar, and Carter 2016; Goldstein, Navar, Pencina, et al. 2016). A recent meta-analysis, for example, did not find systematic benefit from machine learning in comparison to logistic regression (Christodouloua et al. 2019). Yet there is also optimism about the potential for artificial intelligence methods in medicine (He et al. 2019) in general, as well as cardiology specifically (Johnson et al. 2018).

Building on Mark et al. 2018, we sought to assess the performance of machine learning (ML) methods at predicting MACE among emergency department patients with chest pain. Could ML improve upon existing validated risk scores through a more complex integration of predictors that can better estimate MACE risk? To what extent is hyperparameter optimization necessary to achieve strong ML performance?

Our clinical objective was to maximize the pool of low-risk patients that are accurately predicted to have less than 0.5% MACE risk and may be eligible for reduced testing. The primary threshold of 0.5% risk has previously been identified as an acceptable risk by a majority of emergency physicians for early discharge (Than, Herbert, et al. 2013). Using a risk of 0.5% as the test threshold will inherently lead to a negative predictive value of greater than 99.5%, provided that the risk prediction is well-calibrated in the target population. We also examined secondary thresholds of 1.0% and 2.0%.

A reasonable assessment of ML performance could only be made in comparison to realistic alternative options. We compared ML performance to simpler indicators of risk: key biomarkers (troponin, electrocardiogram), validated clinical risk scores (History, ECG, Age, Risk factors and Troponin [HEART] and Emergency Department Assessment of Chest pain Score [EDACS]), decision trees, and logistic regression.

If machine learning can demonstrate improved discriminative performance compared to logistic regression and related methods, along with appropriate calibration, its next hurdle for adoption is to provide interpretability. Clinicians may be willing to forgo maximum predictive accuracy for the sake of understanding how individual predictors influence the output of the algorithm. With analytical effort it may be possible to provide sufficient interpretability for clinicians to accept the complication of machine learning and the benefit of the (potentially) improved predictive accuracy. To facilitate interpretation, we explained the models through prediction-based variable importance ranking and accumulated local effect visualization. If simpler algorithms remain preferred, the ML results can at least approximately the best achievable performance, and so serve as benchmark standards when considering more restrictive algorithms.

Certain analytical characteristics would be important to arrange in order for ML to potentially improve upon simpler options. First, it was important to extract a broader set of granular predictor variables than were used by existing scores. Extensive predictor sets give ML the potential to capture interactions and nonlinear relationships that are missed by linear or additive approaches, perhaps relevant only to certain subgroups of patients. Further, ML may statistically identify novel predictors that have been missed by existing scores or the broader literature, or whose predictive impact was too small, in too complex a form, or underrepresented in terms of sample size to be detected by non-ML methods. The expansion of electronic health records (EHRs) also makes broader covariate collection more feasible and relevant than was possible prior to EHRs, while also facilitating more granular measurement of variables (E. H. Kennedy et al. 2013).

It is also important for variables be measured on a fine-grained scale, which gives ML the opportunity to detect novel cut-points or thresholds that improve performance. Variables should be kept as their original continuous measurements rather than dichotomized or discretized into qualitative levels (Senn 2005). For example, a predictor such as body mass index (BMI) loses substantial information when it is dichotomized into an indicator of high-BMI or the absence of high-BMI. A single threshold chosen for for that dichotomization may not be optimal for certain subgroups or regions of risk. One of the benefits of ML is that it can identify thresholds in a data-adaptive way, allowing it to better approximate unknown or ill-understood physiological processes. That said, very high cardinality variables can result in overfitting and slow down the training of certain machine learning algorithms, such as decision trees, that test each unique value as a possible subgroup splitting threshold. It may be beneficial to reduce the cardinality of granular continuous variables through histogram binning that scales with the dataset size, e.g. sample size / 1000 or log(sample size) * 10.

2 Data and Methods

2.1 Source of data

Our study was sourced from the electronic health record (EHR) of 21 emergency departments (EDs) within Kaiser Permanente Northern California, an integrated health care delivery system with over 1 million annual ED visits. patient visits to

2.2 Participants

All adult patients were retrospectively included if they had received cardiac troponin 98 testing in the emergency department and either presented with a chief complaint of 99 chest pain or chest discomfort, or whose ED physician had assigned them a primary or 100 secondary ICD-coded diagnosis of chest pain. The later inclusion criterion is important 101 because patients may complain of "anginal equivalents" (such as shortness of breath) in 102 lieu of overt chest pain (Amsterdam et al. 2010). The initial inclusion pool had a 60-day 103 MACE rate of 8.0%. Patients were excluded if they had a MACE diagnosis in the ED or 104 within 30 days prior to ED visit, alternative non-ACS diagnoses at index visit (e.g. 105 pneumonia, pneumothorax, or traumatic injury), could not be tracked due to lack of 106 active health plan membership during the study (except in cases of death), or had a 107 troponin I > 99th percentile upper limit of normal given the dominant predictive value 108 of elevated troponin values for adverse outcomes in both patients with acute coronary 109 syndromes and in the general population (Bonaca et al. 2010; De Lemos et al. 2010). 110 Patients were excluded if their smoking status was unknown, which was viewed as a key 111 marker of low-quality data. The final study cohort consisted of 116,764 patients with a 112 60-day MACE incidence of 1.88%. A fourth-generation troponin assay was used during 113 the study period (AccuTnI+3, Beckman-Couleter, Brea, CA, USA). 114

2.3 Outcome

Our primary outcome was cumulative MACE incidence within 60 days of the index visit. 116 We defined MACE as myocardial infarction, cardiogenic shock, cardiac arrest, or death. 117

2.4 Predictors

We used a total of 74 predictors sourced from the electronic health record, including vitals, labs, history, qualitative interpretation of ECG imaging, regular expression-based extraction of features from clinical notes, demographics, and missingness indicators (20). These predictors are detailed in Table ??.

2.5 Missing data

Missingness rates for each predictor are listed in Table ??. We created missingness indicators for each predictor, which marked the observations that were missing a value. Inclusion of missingness indicators often improves predictive performance (Agor et al. 2019). That matrix of missingness indicators was analyzed for perfect collinearity, and duplicate indicators were dropped.

Missing predictor values were imputed by factorizing the raw data matrix with generalized low-rank models (GLRM) (Schuler et al. 2016; Udell et al. 2016). GLRM is a generalization of principal component analysis and matrix completion methods and is designed for mixed type data frames that include continuous, categorical, ordinal, and binary variables. GLRM decomposes (factorizes) the original data frame into an X matrix of reduced components and Y matrix of archetypes, including possible penalty

115

93

95

96

97

118

123

3/21

> terms that can induce sparsity (L1) or simply denoise (L2 or quadratic). Multiplying these two factor matrices reconstructs the original data frame, imputing any data entries with missing values. The method used for missingness provides few constraints on the resulting fit and also permits prediction from future data with missing values.

The GRLM hyperparameter settings were chosen through a grid search in which 139 each model was trained on 75% of the data and evaluated on the remaining 25% for 140 accuracy at reconstructing the original observed data matrix. Missingness indicators 141 were not included in the GRLM imputation analysis. Our final GLRM settings were: 50 142 components, quadratic regularization on X with weight 4, and L1 regularization on Y 143 with weight 24. Cells with missing data were then replaced with the reconstructed data 144 matrix from GLRM using the optimal settings.¹ 145

GLRM imputation greatly increased the number of unique values (cardinality) for 146 continuous variables, which would have a negative performance impact on tree-based 147 algorithms that test every unique value for a potential split. To avoid that performance 148 drop, we using penalized histogram binning to bin imputed predictors with high cardinality into up to 200 unique values (Rozenholc et al. 2010). 150

Multiple imputation was not necessary because our scientific goal was to characterize 151 predictive performance for the unimputed outcome variable, rather than to estimate 152 statistical parameters for covariates that were imputed, such as linear regression 153 coefficients (Steverberg 2009; Wang et al. 1992). 154

2.6**Prediction algorithms**

Dozens if not hundreds of other prediction algorithms would be possible to evaluate, but 156 computational time limitations forced us to choose a finite set with reasonable 157 performance expectations. We chose well-known prediction algorithms that have shown 158 strong performance in prior research, including both linear and decision tree-based 159 estimation. The tree-based prediction algorithms were random forest (Breiman 2001), extreme gradient boosting (XGBoost) (Chen et al. 2016), and Bayesian additive 161 regression trees (Chipman et al. 2010). The linear prediction algorithms were generalized additive models (T. J. Hastie et al. 1990) using thin plate splines (Wood 163 2003), and lasso (Tibshirani 1996). 164

Splines have shown competitive performance with tree-based algorithms in prior 165 clinical prediction work due to their ability to identify non-linear, but smooth patterns 166 (Austin 2007). The lasso algorithm (or its generalization the elastic net) is a helpful test 167 of sparsity in the covariates, and a faster & more nuanced variable selection method 168 than best subset or stepwise selection (T. Hastie et al. 2017). Better performance for 169 lasso compared to logistic regression would indicate that feature selection could be 170 helpful for other algorithms, while equal performance could indicate that the extraction 171 of predictors from the EHR was overly restrictive and should be broadened. 172

2.7**Benchmarks**

When evaluating complex algorithms it is important to contextualize their performance 174 by comparing to simpler alternative approaches or benchmarks. If the benchmark 175 algorithms can achieve similar performance then the extra complexity of the statistical 176 machine learning algorithms may not be worthwhile. The improvement of a novel 177 prediction method over standard benchmarks is known as the *skill* of the prediction 178 method (Brier 1950; Murphy et al. 1977; F. Sanders 1963). In clinical prediction the 179 primary alternatives to statistical machine learning are relatively inflexible fits, which 180

135

> include logistic regression, ordinary least squares, individual decision trees, and stratification on key clinical covariates. We tested each of these options, where key covariates were defined as peak troponin, qualitative ECG reading, EDACS score, and HEART score. As a complement to stratification on different subsets of key covariates, we also evaluated logistic regression and decision trees when restricted to these key covariates.

2.8 Stacked ensembling: SuperLearning

When comparing a variety of algorithms an initial choice is to use cross-validation to 188 select the algorithm with the best out-of-sample performance. A more nuanced decision 189 would be to consider a weighted average of multiple algorithms - creating a team of 190 algorithms whose contribution to the prediction is based on optimizing out-of-sample 191 performance on a certain statistic. That is the nature of stacked ensembles (Breiman 192 1996; Wolpert 1992), sometimes referred to as the Super Learner algorithm (van der 193 Laan et al. 2007). Rather than restrict our prediction machine to a single algorithm, we 194 create a weighted average across all tested algorithms, and estimated weights based on 195 an optimization goal so that they minimize a chosen performance statistic on test data. 196 We chose to optimize the Brier score (i.e. mean-squared error) in our ensemble, using 197 convex weights based on a non-negative least squares meta-learner. Optimizing on Brier 198 score includes a focus on both discrimination and calibration for the ensemble (Murphy 199 et al. 1977). A convex combination of algorithm weights ensures that predictions fall 200 within the convex hull of the constituent learners, while also inducing sparsity - i.e. 201 algorithms can have zero weight. 202

2.9 Hyperparameter tuning

Prediction algorithms often have multiple hyperparameter settings that adjust the 204 estimation procedure in different ways. Those hyperparameters are not estimated from 205 the data, but rather must be specified a priori by the analyst. While software 206 implementations will typically provide a default value for each hyperparameter, there is 207 no reason to believe that the default values are effective for the current dataset. 208 Customizing the hyperparameter configuration to the current dataset can allow the 209 algorithms to adapt to the available sample size, number of predictor variables. 210 measurement error in the predictors, sparsity in predictor relevance, and correlation 211 structure of the predictors. Hyperparameters are often chosen by fitting the algorithm 212 with different configurations and selecting the configuration that maximizes accuracy on 213 held-out data, such as through cross-validation. The benefit of hyperparameter tuning 214 is believed to vary by algorithm, which is referred to as the *tunability* of the algorithm 215 (Probst, Boulesteix, et al. 2019). Random forest, for example, is believed to work well 216 with default hyperparameters but also can benefit from hyperparameter tuning, 217 particularly to reduce overfitting (Probst, Wright, et al. 2019; Segal et al. 2011). 218

Hyperparameter tuning is inherently a computationally intensive process, as it 219 involves fitting the algorithms many different times, and varies based on the number of 220 hyperparameters (dimensionality) as well as number of the unique values tested for each 221 hyperparameter (resolution). Further complexity is involved if one considers that some 222 hyperparameters may be more important than others for a given algorithm. Given the 223 role of hyperparameters in modifying the performance of prediction algorithms, caution 224 is warranted when generalizing algorithm performance characteristics from individual 225 studies (e.g. algorithm X outperforms algorithm Y), particularly when hyperparameters 226 are left at their default values and therefore are not customized to the given dataset. 227

For this work we adopted a hyperparameter tuning approach using *nested* ensembling. Much as using a weighted ensemble of different algorithms may be

228

229

187

> preferable to selecting the single best-performing algorithm, using a weighted ensemble 230 of hyperparameter settings for a given algorithm may yield improved performance 231 compared to selecting a single set of hyperparameters. With that concept in mind we 232 created small grids of hyperparameter configurations and estimated a SuperLearner 233 ensemble for a given algorithm in which the ensemble weights selected the 234 hyperparameter settings that maximized out-of-sample performance. This ensemble of 235 hyperparameter settings could potentially rely on a single configuration due to the 236 sparsity induced by the convex combination, or the optimization could distribute the 237 weighting across multiple configurations if such a weighting improved performance over 238 a single selected configuration. Another benefit of the nested ensembling is that it limits 239 the number of learners that are analyzed in the outer SuperLearner ensemble, which can 240 conserve power and mitigate overfitting in the meta-learning process (i.e. allocation of 241 weights in the convex combination). 242

> We used the ensemble hyperparameter tuning approach for random forests, xgboost, and individual decision trees. The random forest grid consisted of 9 configurations: minimum node size $\in \{5, 20, 60\} \times \text{covariates sampled} \in \{4, 8, 16\}^2$. The xgboost grid consisted of 8 configurations: number of trees $\in \{250, 1000\} \times \text{maximum tree depth} \in \{2, 4\} \times \text{shrinkage} \in \{0.05, 0.2\}$. The decision tree grid consisted of 12 configurations: complexity parameter $\in \{0, 0.01\} \times \text{minimum split} \in \{10, 20, 80\} \times \text{maximum tree}$ depth $\in \{10, 30\}$.

2.10 Evaluation

We evaluated alternative options for risk prediction based on their discrimination, calibration, and clinical utility. Nested cross-validation with 5 folds was used to conduct the discrimination and calibration analyses. While bootstrap estimation has been promoted for evaluation of clinical prediction models (Austin and Tu 2004; Steyerberg, Harrell Jr, et al. 2001), recent work has shown that the bootstrap can be biased for evaluating the performance of highly adaptive ML algorithms estimators such as random forests (Benkeser et al. 2019). 251

2.10.1 Discrimination

We chose area under the precision-recall curve (PR-AUC, also known as average 259 precision) as our primary performance metric for evaluating discrimination, because it 260 highlights performance differences that may be missed by ROC-AUC with imbalanced 261 data (Cook 2007; Saito et al. 2015). We included area under the receiver operating 262 characteristic curve (ROC-AUC or the concordance statistic) as our secondary performance metric, which remains highly popular and interpretable (Janssens et al. 264 2020). As an exploratory metric we also estimated the adjusted Brier score (index of 265 prediction accuracy) which integrates discrimination and calibration into a single metric 266 (Kattan et al. 2018). We visualized improvements in discriminative performance using 267 density plots of the calibration slope (Steyerberg, Vickers, et al. 2010). We did not 268 conduct a reclassification analysis due to recognized limitations (Hilden et al. 2014; Kerr 269 et al. 2014; Leening et al. 2014; Pepe et al. 2015). 270

2.10.2 Calibration

Our clinical use case was centered on a risk threshold of 0.5% to classify patients as "low risk" in order to qualify for early discharge. Because of that scientific goal, it was especially important to compare the model's predicted risks to the observed risks, i.e.

250

258

²The number of covariates sampled (i.e. mtry) was based on the formula: floor($\{0.5, 1, 2\} \cdot \sqrt{p}$) where p is the total number of covariates.

> its calibration (Lichtenstein et al. 1981) - also known as reliability (Brier 1950; Murphy et al. 1977) or external correspondence (Yates 1982). We assessed the calibration of predicted probabilities in two ways: 1) calibration curve visualization, 2) calculation of the index of prediction accuracy (IPA), a transformation of the Brier score (Kattan et al. 2018). We did not conduct a Hosmer-Lemeshow group-based calibration test due to its recognized limitations and recommendations against its use (Kramer et al. 2007; Van Calster et al. 2019).

2.10.3 Clinical utility

The planned clinical use of the prediction model was first to assess eligibility for early discharge among low-risk patients. Accurately estimating the risk of MACE for patients would allow those low-risk patients to be discharged and avoid additional unnecessary workup, freeing up resources (clinical attention, testing capacity, etc.) for higher risk patients. Low risk was generally defined as being below a 0.5% well-calibrated probability of MACE within 60 days, with less conservative thresholds of 1% and 2% as additional options.

Our model needed to balance two trade-offs: 1) false "negatives" in which a patient 290 was identified as low-risk but whose true risk of MACE within 60 days was above the 291 threshold, and 2) false "positives" in which patients were believed to be above the given 292 threshold but whose true risk was less than the threshold. Errors in the first category 293 have a greater cost than those in the second category, because there is a greater 294 potential detriment to those patients who were discharged early but whose true risk 295 exceeded the threshold. Patients incorrectly estimated to be above the risk threshold, 296 but who are truly low risk, have comparatively minor costs of additional workup, use of 297 clinical resources, and potential to be overtreated. Yet these possible errors are not 298 quite the same as false negative or false positives typically used to assess predictive 299 models: we care about the true, but unknown, risk rather than the observed outcome. 300 Under this decision-making calculus a patient whose true risk is correctly predicted to 301 be below the clinical threshold, and is therefore discharged without additional workup, 302 but who ends up having a MACE would still have been managed appropriately. 303

This suggests that the absolute or squared error of the patient's predicted risk versus 304 true risk, particularly near the clinical threshold, would be reasonable loss functions to 305 translate into clinical utility. Miscalibration near the clinical threshold needs to be 306 avoided, whereas miscalibration away from the threshold does not affect the decision. 307 As the expected value of that loss approaches zero we would see that the number of 308 false negatives and false positives (in terms of risk above or below a threshold rather 309 than the observed outcome) also approaches zero. We could target a specific threshold 310 by focusing on patients on the incorrect side of the threshold and averaging the error in 311 their risk prediction, possibly including differential weights for each side of the threshold 312 to account for different costs to the patient. Such a "miscalibration-around-a-threshold" 313 loss function might look as follows: 314

$$\log(Y_i, \hat{Y}_i \mid X_i) = \omega_1 \mathbf{1} (P_0(Y_i \mid X_i) < \tau) g \Big(\hat{f}(X_i) - \tau \Big) +$$

$$\omega_2 \mathbf{1} (P_0(Y_i \mid X_i) > \tau) g \Big(\tau - \hat{f}(X_i) \Big)$$
(1)

where:

- Y is the observed outcome and X is the set of predictors, *i* indexes each patient in the sample,
- $P_0(Y_i \mid X_i)$ is the true risk of patient i,

7/21

315

- $\hat{f}(X_i)$ is the predicted risk of patient i from a given estimator \hat{f} , 319
- τ is the clinical threshold (e.g. 0.5%), 320
- q is a function such as the identity, squared value, or absolute value function, 321
- ω_1 is the differential cost for low-risk patients who are kept for further workup, 322
- ω_2 is the differential cost for high-risk patients who are incorrectly discharged 323 early, 324

We do not know the true risk for any patients, but we can estimate it within our 325 sample by fitting a semi-parametric smooth function (e.g. lowess) to estimate the true 326 probability of the outcome given the estimated predicted probability, equivalent to what 327 is done during calibration analysis. 328

If multiple decisions were to be made based on the estimated risk, we might sum this 329 loss over each decision. Alternatively we might use a threshold-free loss function, such 330 as: 331

$$\log(Y_i, \hat{Y}_i \mid X_i) = g\left(\hat{f}(X_i) - \tau\right)$$
(2)

In this work we focus on the threshold-free loss with absolute value as the transformation function g.

Interpretability 2.11

Beyond the statistical performance of a clinical prediction, it can be important to 336 provide an explanation or overview of how a model generates its predictions. Interpretation is desirable first because it can provide evidence that the model is working as expected, which can improve the trustworthiness of its predictions for clinicians, patients, or collaborators. Interpretation may also lead to scientific insights about how predictors are related to the outcome, which could be conceptualized as causal pathways, data generating processes, or biological mechanisms. Interpretation can further inform the data export and cleaning processes, such as identifying extreme values, data entry errors, or outliers, or suggesting additional predictor variables to 344 incorporate into the model.

Methods of interpretation can be model-specific or model-agnostic. For models within the family of linear regression, one might provide the estimated beta coefficients 347 for each predictor, along with their associated confidence intervals and p-values. Interpretation becomes less straightforward as models become more complex, such as with interaction or polynomial terms in a regression, random forest or boosted tree models with hundreds or thousands of non-linear decision trees, or splines in which ranges of a given predictor might have different coefficients.

In this work we focus on two complementary forms of model interpretability: variable importance ranking and accumulated local effect plots, as described below.

2.11.1Variable importance ranking

Prediction-oriented variable importance rankings order the predictor variables by their 356 contribution to a model's prediction, providing evidence as to which predictors were 357 relied upon the most by the algorithm. Such rankings could be used as a form of 358 confirmatory analysis if a hypothesized ranking were created prior to data analysis, 359 which could formally identify predictors that differed from their expected importance. 360

353

354

It may also be helpful to understand how a model's prediction varies over the values of 362 individual predictors, particularly continuous predictors with a wide range or large 363 number of unique values. Partial dependence plots (PDPs) as proposed by Friedman 364 (2001) are commonly used to provide this type of interpretability, but they can yield 365 flawed results because they make a key unrealistic assumption that features are 366 statistically independent of each other (Molnar 2020, p. 5.1.3). Accumulated local effect 367 (ALE) plots are a recently developed method that avoids that limitation of PDPs, by 368 counterfactually modifying observations that lie within a nearby kernel neighborhood of 369 the current predictor's value of interest (Apley et al. 2019). Following the variable 370 importance ranking, we visualize the contribution of high-importance continuous 371 variables using accumulated local effect plots. 372

3 Results

3.1	Model performance	374

3.1.1 Discrimination

Figure 1 displays the estimated precision-recall area under the curve (PR-AUC) 376 PR-AUCs and 95% confidence intervals for each combination of features and estimation 377 algorithm. The MACE mean on the training sample represents the baseline PR-AUC, 378 which was 1.88%. The SuperLearner ensemble achieved the highest estimated PR-AUC 379 (0.148, 95% CI [0.126, 0.170]), followed by the random forest with hyperparameter 380 tuning (0.144, [0.125, 0.164]), the default random forest (0.143, [0.122, 0.165]), and the 381 tuned XGBoost (0.138, [0.116, 0.160]). By comparison the PR-AUC for logistic 382 regression was 0.120 [0.103, 0.137], noticeably lower than the ensemble. Point estimates 383 and confidence intervals are listed in Supplemental Table ??. 384

373

Figure 1. Comparison of cross-validated discriminative performance using PR-AUC metric, with 95% confidence intervals.

Figure 2. Comparison of cross-validated discriminative performance using precision-recall curves for a subset of learners.

For our secondary discrimination metric, cross-validated ROC-AUC was calculated

> and is displayed in Figure 3 (LeDell et al. 2015). The SuperLearner ensemble again achieved the highest performance (ROC-AUC = 0.866, 95% CI [0.859, 0.873]), followed by tuned random forest (0.860, [0.853, 0.867]), tuned XGBoost (0.859, [0.852, 0.866]), and BART (0.859, [0.852, 0.866]). The ROC-AUC for logistic regression (0.842, [0.834, 0.850]) was significantly lower than the ensemble (p = X). Point estimates and confidence intervals are listed in Supplemental Table **?**?.

Figure 3. Comparison of cross-validated discriminative performance using ROC-AUC metric, with 95% confidence intervals. The simple mean had a standard AUC of 0.5 and is omitted from the plot.

3.1.2 Calibration

We visually compared the predicted risk of the SuperLearner ensemble to the lowess-smoothed observed risk in figure 4. The red line is the target calibration in which predicted risk is equal to observed risk. The blue line shows the lowess-smoothed observed risk for each value of the predicted risk.

#	Learner	Mean	SD	Min	Max
1	Random forest	0.2516	0.0765	0.1815	0.3749
2	Random forest tuned	0.2488	0.0828	0.1449	0.3737
3	XGBoost	0.1959	0.0378	0.1506	0.2378
4	BART	0.1824	0.0535	0.0993	0.2316
5	Splines	0.0748	0.0685	0.0000	0.1764
6	Logistic reg.	0.0429	0.0309	0.0000	0.0720
7	Stratification (trop., ECG, EDACS)	0.0036	0.0080	0.0000	0.0178

Table 1. Distribution of algorithm weights across ensemble cross-validation replications

Figure 4. Calibration plot comparing predicted risk to observed risk

The median predicted risk was 0.64%, with a first quartile of 0.2% and third quartile of 2%. Our primary threshold of scientific interest was 0.5% for possible early discharge. Given those low risk levels, it would be best to "zoom in" our visual calibration review to that region. We show a zoomed calibration plot as Figure 5.

Figure 5. Zoomed calibration plot comparing predicted risk to observed risk. Clinical thresholds of 0.5%, 1%, or 2% risk are noted by blue vertical lines.

Finally, we include a exponential-scale calibration plot (Figure 6) with calibration confidence intervals after grouping patients into 10 groups based on predicted risk, consistent with TRIPOD guideline recommendations (Collins et al. 2015). Due to the substantial class imbalance the exponential scaling of axes allows easier comparison across the probability range, although it may be less intuitive due to the shifting of scales. For example, the width of confidence intervals is counterintuitive for visual comparison due to the dynamic scaling, but the amount of information provided is visually consistent throughout the plot.

Figure 6. Exponential-scale calibration plot comparing predicted risk to observed risk with grouped 95% confidence intervals. Clinical thresholds of 0.5%, 1%, or 2% risk are noted by blue vertical lines.

Variable	Missingness	Error GLRM	Error Median	Percent reduction
HbA1c	59.8	0.088	1.628	94.6
Triglycerides	46.9	0.039	0.528	92.6
HDL	43.5	1.077	14.815	92.7
Total Chol.	42.7	7.961	45.762	82.6
LDL	38.8	4.158	37.291	88.8
GFR	8.8	0.286	11.699	97.6
Trop. 3HV	2.7	0.001	0.008	90.2
ECG	1.8	0.000	0.729	100.0

Lowest SBP	0.1	0.458	18.673	97.5

Table 2. Comparing missing value imputation using GLRM versus median/mode

As a statistical complement to the visual examination, we also calculated mean 417 absolute error (MAE). MAE is the sample mean of the absolute difference between the smoothed observed risk (Risk₀) and the predicted risk (Risk_P). 418

$$\frac{1}{n}\sum_{i=1}^{n} |\operatorname{Risk}_{O}(i) - \operatorname{Risk}_{P}(i)|$$
(3)

We found an MAE of 0.19% with a lowess smoothing span of 0.05 (low smoothing), and an MAE of 0.14% with a smoothing span of 0.20 (moderate smoothing). These statistics indicate that the ensemble risk prediction was typically miscalibrated by about 0.17 percentage points.

3.1.3 Missing data imputation

We evaluated the benefit of the more complex GLRM-based imputation by comparing the imputed value to the known value, among variables with missingness. The root mean-squared error metric was calculated for each variable, and for both GLRM and median/mode imputation methods. We could then estimate the percentage improvement in RMSE for the GLRM imputation. Results in Table 2 show a notable improvement in RMSE for every variable, with the exception of the obesity binary variable.

3.2 Interpretation

3.2.1 Variable importance ranking

As discussed earlier, our objective for the variable importance analysis was to understand which variables were most influential on the prediction of our final model. Providing that ranking could improve the interpretability of the risk prediction, allowing for confirmation that the results are reasonable and possibly yielding additional scientific insights. However, our final model is quite complex: it is a weighted average of multiple versions of random forests, xgboost models, bayesian additive regression trees, etc. In this work we provide rankings for the top two estimation

424

431

> algorithms: random forest and xgboost. We used the optimal hyperparameter settings 440 from cross-validated analysis.

Interestingly we see rather different results between the two algorithms, which 442 supports the hypothesis than an ensemble of multiple algorithms could achieve better 443 performance than selecting a single estimation algorithm. Both algorithms place high 444 emphasis on the EDACS and HEART risk scores, demonstrating the benefit of 445 including those scores along with the underlying predictors. Different versions of the 446 cardiac troponin predictor are emphasized by the two algorithms: random forest focuses 447 on 3-hour troponin whereas xgboost focuses on peak troponin. ECG reading is 448 emphasized by xgboost but not random forest. Both algorithms make use of lipid profile 449 predictors (LDL, HDL) and vital signs (pulse, respiration) that are not included in the existing risk scores. The random forest makes use of certain missingness indicators, which are often indicative of the quality of a patient's records, while xgboost does not. 452 Also noteworthy is the lack of pain-related characteristics sourced from clinical notes in 453 the top predictors, a difference from prior work highlighting their importance at predicting MACE (Amsterdam et al. 2010).

Accumulated local effects 3.2.2

The accumulated local effect method visualizes the conditional relationship of top predictors to the ensemble's prediction, across their range of values.

4 Discussion

The next step in model evaluation is to conduct one or more external validations of the discrimination and calibration of the model predictions. This validation might include future retrospective cohorts at the current study location (temporal validation), although preferably cohorts sourced from other regions or EHRs (geographical or institutional validation) (Moons et al. 2012). We hope to collaborate in the future with groups interested in such validations.

In future work we plan to expand the machine learning in several ways. The 466 ensemble weighting could specifically optimize PR-AUC. Incorporating feature selection 467 may benefit the simpler algorithms by removing unhelpful predictors. Feature 468 engineering might be beneficial as well, such as creation of interaction terms or even 469 incorporation of the principal components from the GLRM imputation. Due to 470 computational limitations we were not able to conduct hyperparameter tuning on the 471 BART learner, which likely would provide some performance benefit. We are optimistic 472 that random search or model-based search (e.g. Bayesian optimization) rather than grid 473 search could provide even stronger tuning of algorithm hyperparameters across a higher 474

> number of dimensions. Evaluation of the GLRM imputation could be further 475 contextualized through comparisons to additional imputation methods, especially 476 principal component analysis, k-nearest neighbors, multiple imputation, and 477 variable-specific supervised models (e.g. OLS or random forest). Additional machine 478 learning algorithms could be explored, such as LightGBM, extremely randomized trees, 479 and multivariate adaptive regression splines. The variable importance ranking could be 480 streamlined through a Random Forest-style permutation importance analysis of the 481 SuperLearner ensemble itself, or through a targeted learning method such as vimp 482 (Williamson et al. 2017) or varimpact (Hubbard et al. 2018). 483

> The model might also benefit from a broader sample that includes higher risk patients, which were not included in this study. Calibration might be improved through 485 targeted learning-based adjustment (Brooks et al. 2012). Cross-validated estimation of discrimination performance could be improved through cross-validated targeted maximum likelihood estimation (Benkeser et al. 2019).

5 Conclusion

In this work we explored the benefit of complex machine learning algorithms at 490 predicted major adverse cardiac events in patients with chest pain. We found that the 491 ML algorithms were able to achieve improved discrimination compared to simpler 492 baselines such as logistic regression, decision trees, or stratification on individual 493 predictors. Combining multiple algorithms into an ensemble estimator yielded the best 494 performance, and rather than select optimal hyperparameters we created an ensemble of 495 algorithms across different hyperparameters. We demonstrated the surprising 496 effectiveness of generalized low-rank models for imputation of missingness in 497 EHR-sourced patient data. Finally, we provided interpration of how the ensemble's 498 prediction is generated through two methods: ranking the predictors by their 499 contribution to predictive performance, and visualizing the dose-response effect of 500 continuous predictors with accumulated local effect plots. 501

The cleaning and analysis code for this project has been translated to use a public dataset and is available online at https://github.com/ck37/Predictive-Modeling-in-R. Functions to calculate PR-AUC, ROC-AUC, index of prediction accuracy (IPA), and Brier scores for cross-validated SuperLearner ensembles are provided in the open source R package ck37r (C. J. Kennedy 2020).
