KEY MESSAGES

- There has been concern, and much heated debate, on the possible negative effects of restrictions, stay-at-home orders and lockdowns during the COVID-19 pandemic.
- Most published studies on health impacts of restrictions and lockdowns are low quality and often severely biased.
- Focusing on the few studies that approximate a change in restrictions alone (i.e. not the impact of the pandemic per se), we see clear adverse impacts of lockdowns on intimate partner violence and physical activity. Regarding diseases, road traffic crashes decrease, and anxiety increases.
- A discussion driven by science (not politics) is urgently needed on what lockdowns can deliver, their limitations and how to optimally deploy them – along other public health strategies – in the fight against COVID-19.

Contributors and sources

The authors have all been involved in researching aspects of the covid-19 pandemic and response. DA and AK are epidemiologists and have been part of the Victorian Department of Health COVID-19 Public Health Intelligence Team. PA is a health economist involved in evaluating the economic impact of the pandemic. NG is a professor of public health and physician. He has provided expert advice to health agencies on COVID-19 policy, and commentary via science and mass media. TB has been a prominent epidemiological commentator in Australia has been involved in providing modelling underpinning the Victorian Department of Health roadmap out 111 days of lockdown and to achieve elimination. DA, AK and PA designed and run the literature searches in agreement with NG and TB. DA coordinated study selection, data extraction and drafted the paper. All authors debated the findings to reach agreement and contributed to the final version of the manuscript.

The indirect health impacts of COVID-19 restrictions: a strong debate informed by weak evidence

Standfirst

Driss Ait Ouakrim and colleagues argue that the vast majority of studies evaluating the unintended effects of COVID-19 restrictions and lockdowns are low quality, prone to severe bias and, therefore, of limited use to health policy making.

Policies to restrict movements and contact between people have been a common response to control the spread of SARS-CoV-2 in many countries.¹

The stringency of these measures ranges from recommendations for people to observe physical distancing and self-isolate if symptomatic, to policies imposing strict stay-at-home orders ('lockdowns'), school closures, business restrictions and border controls.²

These restrictive policies, including lockdowns, have been essential to prevent health services being overwhelmed and to save lives.^{3, 4} They have even enabled some countries to eliminate community transmission of the virus.⁵ What remains unclear, however, are the potential unintended health harms associated with such policies.

Public health authorities and commentators have raised the alarm – as early as the first lockdowns in Wuhan – on the indirect health harms that might result from lockdown policies.⁶ The potential mental health impacts, ranging from loneliness and anxiety through to severe depression and even suicide, have been raised as major concerns.^{7, 8} Other proposed harmful effects have included cardiac conditions, delayed screening, presentation or treatment for cancers, intimate partner violence, increased consumption of ultra-processed foods, alcohol, tobacco and illicit substances.

But what is the actual quantitative evidence on these harms? To answer this, we argue, requires thinking counterfactually before considering approaching the plethora of published studies on this topic.⁹

Counterfactual reasoning and the net health effect of lockdowns

Health impacts during lockdown are a blend of the effect of the lockdown itself (the relevant target for causal inference) and the general effect of the pandemic. For example, people's mental health may be adversely impacted by fear and uncertainty of the pandemic, plus any additional impact of restrictions per se. We want to identify the unintended causal effects (good and bad) of restrictions all other things held constant. Whilst no randomised trials have approximated this, we use natural experiments¹⁰, namely:

- Comparisons over time between residents in the same place during the pandemic, with varying restrictions (i.e. changing exposure) but otherwise similar circumstances (i.e. an absence of time varying confounding, either by design or statistical adjustment).
- Comparisons across places (e.g. states of a country) of similar populations with similar SARS-CoV-2 infection rates and similar other circumstances, but variation in levels of restriction.

That is, we need to find populations that are exchangeable with each other, and only vary in terms of the level of restrictions. This rules out many cross-sectional surveys. Furthermore, many studies that purport to show impacts of restrictions contain significant biases. For example, people cannot be blinded to their own lockdown status which means that subjective measures such as feelings of anxiety are prone to recall bias whilst rapidly conducted internet recruitment surveys are typically not representative of the population (i.e. selection bias).

State of the evidence

To hold such a counterfactual ruler up against the available evidence, we searched the literature for studies meeting or approximating the counterfactual described above. First, we selected risk factors and diseases that have a plausible independent association with COVID-19 policy responses, and that are likely to contribute to a non-negligible health burden: five risk factors (alcohol consumption, body mass index, intimate partner violence, physical activity and tobacco smoking); five health seeking behaviours (screening for melanoma, breast, cervical, colorectal and lung cancer); and ten disease/injury groups (anxiety and depression, chronic obstructive pulmonary disease (COPD), falls, ischemic heart disease (IHD), self-harm, stroke, suicide and road transport injuries).

The vast majority of the existing literature up to 21 January 2021 was low quality and/or contained strong bias (see Appendix for details), leaving only 42 articles. Of these, 28 were comparisons of before with during the pandemic – but were still too weak due to having two or more potentially substantial biases (confounding, measurement error, or selection). This left only 14 studies meeting our strict criteria, and still the majority of these were before-COVID-19 to during COVID-19 comparisons prone to residual confounding.

Consequences

Starting with the fourteen ‘best studies’, wherever possible we converted the study finding into a percentage change for the equivalent of severe restrictions (typically referred to as stage 3 or 4 lockdown) compared to minor restrictions only (see Appendix for details). Where the conversion was not possible, the percentage change was plotted as reported in the study. Figures 1 shows these results for risk factors and diseases.

1) Higher risk of intimate partner violence

Two well designed before-after studies conducted in Spain¹¹ and Italy¹² showed a sharp increase in the number of women reaching out for help to anti-violence centres. The analyses demonstrate a surge in the number of calls (ranging from 41% to 191%) to these centres from women experiencing violence or in a threatening environment during lockdown periods. Both studies were able to access data from all centres operating in their respective countries, which reduces the level of potential measurement error and virtually eliminates risk of selection bias. The findings are in line with many reports and initiatives highlighting the higher risk of violence against women during the COVID-19 crisis, and the need to prevent what has been termed as the “shadow pandemic”.¹³

2) Lower physical activity

As one would expect, restrictions and lockdowns lead to a substantial drop in the average level of physical activity. The four studies¹⁴⁻¹⁷ we include used different measures of physical activity but all reported a reduction (ranging from 7% to 40%). The analyses were based on specific population groups (e.g. medical student, or patients with chronic condition) which might limit the generalisability of their results. What we don't know, however, is how lower physical activity during lockdowns will affect future population health outcomes. Modelling studies are needed in this area to estimate the potential effects of reduced physical activity and help design and evaluate future mitigation strategies.

3) No convincing impact on alcohol and tobacco use

The studies reporting on the effect alcohol consumption and tobacco smoking during lockdown periods provide conflicting results for these two risk factors. Smoking habits do not seem to have been impacted by the lockdowns. Jackson et al.¹⁸ reported a 7% increase in smoking prevalence (95% CI: 5%-19%), while Niedwiedz et al.¹⁹ showed a reduction of 11% (95% CI: -18% to -3%). There was similar uncertainty around alcohol consumption. Colbert et al.²⁰ identifies a 7% reduction in the alcohol purchasing during the lockdown, while Niedwiedz et al.¹⁹ found changing patterns in consumption that might cancel out any effect.

4) Reduced number of injuries due to falls and road traffic

A clear positive health effect of restrictions and lockdown policies seems to be the substantial reduction in the number of road traffic injuries as shown by two studies analysing the number of emergency department admissions in Ireland and Australia. This effect likely results from the reduction in mobility induced by lockdowns and minimal economic activity.²¹ However, the US study by Quershi et al.²² which analysed data from the Statewide Traffic Accidents Record in Missouri showed no effect of the lockdown on the number of road traffic accidents resulting in serious or fatal injuries. Which suggest that the wider context in which a lockdown is implemented might determine how it impacts road traffic injuries, e.g. a highly car dependent culture may actually use road travel to socially isolate.

Other beneficial effects include a reduction in trauma admission due to falls. Jacob et al.²³ reported a 21% reduction observed in a large trauma centre in Australia compared to pre-lockdown levels. This also seems a very plausible consequence of lockdowns, if indeed people are mandated to stay at home and limit their movement to the strict minimum.

5) Likely higher level of anxiety

We identified only one study investigating the effect of lockdown on anxiety that met our counterfactual criteria. Papandreou et al.²⁴ compared the levels of anxiety using two parallel surveys: in Spain, while the country was experiencing a strict lockdown, and in Greece where minimal restrictions were in place. The prevalence of anxiety in the Spanish population was 88% (95% CI: 27%-182%) greater than in the Greek population. The potential risk of confounding from the pandemic itself is likely to be low, under the assumption that the pandemic induces a similar level of anxiety in the two populations. However, the study does not adjust for any pre-pandemic variation in anxiety levels.

6) Little evidence of effect on depression, self-harm and suicide

The three studies reporting on depression²⁴, self-harm²³ and suicide¹⁹ suggest that lockdowns have no immediate effect on the prevalence of these conditions. While this finding seems plausible in the short term and for a given period of lockdown, it does not provide definitive evidence of absence of effect. First, there remains uncertainty on how the experience of lockdown might translate in the long-term – in particular on prevalence of depression; and second, how repeated periods of restrictions and lockdowns – as has been experienced in many countries – might impact these three conditions and mental health in general.

Box 1: Disruptions in cancer care and prevention

- There is strong and consistent evidence, from a variety of countries, that disruptions related to the pandemic have led to substantial reductions in cancer screening, diagnoses and treatment. Denmark, for example, saw a 33% (95% CI:26%-40%) reduction in incident cancers between March and May 2020 compared to the same months in the previous five years.²⁵ In the Netherlands, cancer diagnoses (across all sites, excluding skin cancer) were 20% lower than in 2019.²⁶ In the United States, the weekly number of newly identified cancers declined by 46% for 6 cancer types combined (i.e. breast, colorectal, lung, pancreatic, gastric, and oesophageal).²⁷ Similar declining trends in referrals and diagnosis have been consistently reported in other countries and for individual cancers.²⁸⁻³⁰ However, we are not aware of studies that separate out the effect of restrictions per se on cancer service utilisation, from that due to the wider pandemic.
- Modelling studies have also evaluated the potential impact of pandemic-related disruptions to cancer treatment and prevention. In the UK for example, a 3 month delay in referral/treatment is expected to result in 4,500 lives lost over a period of 10 years (Sud et al.).
- These delayed presentations result from both increased pressure that the pandemic has placed on health services and the fear of attending them. How much of any contemporaneous impact is due to the causal impact of restrictions, as opposed to fear of contacting people with SARS-CoV-2 and health services capacity being exceeded, is unknown. Moreover, there is a case that restrictions and lockdowns – by reducing future case loads – will in the medium term increase screening compared to a counterfactual of ongoing high case loads disrupting health services.
- In most countries, healthcare resources such as staff were reassigned to COVID-19 leading to negative effects on cancer care and other chronic diseases.³¹ However, even where countries didn't suspend their national cancer screening programmes, uptake decreased possibly out of fear of catching Covid19 or due to assumptions about the lack of capacity in the health system, or presumed closure.
- The specific role that restrictions played in these disruptions to healthcare is less clear. The few studies that investigated the specific contemporaneous effect of the lockdown were likely confounded by the broader effect of the pandemic.

a) Risk factors

b) Diseases and conditions

IPV: intimate partner violence, RTI: road transport injuries. Error bars are 95% CI for those studies giving them, or presenting data allowing us to calculate them.

What is beyond the counterfactual framework?

Relaxing our criteria to include weaker study designs (before-after studies with two or more major likely biases), we considered 32 additional studies. Summaries of their main features and findings are provided in the online appendix. These consistently show that the risk factors worsen during (but perhaps not because of) lockdowns.

The same negative effects were shown for many diseases and conditions, apart from road traffic injuries, for which a substantial reduction was reported, consistent with the results from the higher quality studies.

For six out of 10 conditions considered, the primary outcomes were access to health services, which represents a further limitation to these studies. Health seeking behaviour might not accurately represent change in incidence. For example, mild symptoms of ischaemic heart disease or COPD might be ignored as a result of the pandemic out of fear of going to hospital.

Is the cure, indeed, worse than the disease?

The positive effect of restrictions containing a deadly pandemic is clear. But there is no doubt measures such as lockdowns are highly disruptive at the time and can have profound social, health and economic consequences. They also force policy makers and society as a whole to address challenging ethical and philosophical questions.³² It is well established that public health interventions in general can have unintended harmful effects, reinforce health inequities or even worsen the negative outcomes they set out to address.³³ Our data suggests lockdown's can have both negative and positive consequences such as decreasing road traffic injuries, yet increasing risk of intimate partner violence and reducing physical activity.

However, in the case of the COVID-19 pandemic, what should have been a rigorous and evidence-based discussion between public health experts and policy makers³⁴ about how to best implement a preventive strategy to protect population health, turned into a sterile and highly politicised debate³⁵ between those who support the lockdowns – seeing them as the only way to tackle the pandemic in the absence of effective treatment or vaccine – and those claiming that their unintended consequences are so severe that they cause more harm than the pandemic itself.³⁶

Accordingly, some governments imposed long and unnecessarily harsh lockdowns, even where the harm seemingly outweighed the benefit (e.g. India, Philippines). Other governments perhaps overestimated the negative impact of lockdowns and only used them as a last resort (e.g. France, Germany) or ruled them out as a preventive strategy (e.g. Sweden, Brazil).

Using a counterfactual filter on studies we found little quality evidence to suggest the cure is worse than the disease. However, absence of quality evidence isn't necessarily evidence of absence of negative (or positive) effect. Clearly, we need more quality, natural-experiment data, along with data on delayed health effects, including those resulting from social determinants such education and employment. From our review and analysis, we believe much of this information exist – hidden in governmental and private databases – but has not (yet) been analysed or published.

We urge researchers to try and disentangle the causal impact of lockdowns and restrictions for 'background' COVID-19, to hopefully allow a more scientific (and less political) discussion about what they can deliver, their limitations and how to optimally deploy them – along other public health strategies – in the fight against COVID-19.
