8 **Abstract**

9 The human connectome is the complete structural description of the network of connections and elements
10 that form the ‘wiring diagram’ of the brain. Due to the current scarcity of information regarding laminar
11 end points of white matter tracts inside cortical grey matter, tractography remains focused on cortical
12 partitioning into regions, while ignoring radial partitioning into laminar components. To overcome this
13 biased representation of the cortex as a single homogenous unit, we use a recent data-derived model of
14 cortical laminar connectivity, which has been further explored and corroborated in the macaque brain by
15 comparison to published studies. The model integrates multimodal MRI imaging datasets of both white
16 matter connectivity and grey matter laminar composition into a laminar-level connectome. In this study
17 we model the laminar connectome of healthy human brains (N=30) and explore them via a set of
18 neurobiologically meaningful complex network measures. Our analysis demonstrates a subdivision of
19 network hubs that appear in the standard connectome into each individual component of the laminar
20 connectome, giving a fresh look into the role of laminar components in cortical connectivity and offering
21 new prospects in the fields of both structural and functional connectivity.

22 **Key words:** computational models; connectomics; cortical layers; neuronal structures; anatomical
23 mapping; brain network analysis

24

25

26 **Introduction**

27 The human connectome is the comprehensive structural description of the network of connections and
28 elements that form the human brain's 'wiring diagram'. The importance of exploring the connectome
29 lies not only in uncovering patterns of structural connectivity across the brain, but also in understanding
30 the functional states that emerge from it. For these reasons and more, uncovering the complete human
31 connectome has become a crucial and central mission in neuroscientific research (Sporns et al. 2005).

32 Since its foundation, the Human Connectome Project has lead the mission to map the connectome using
33 non-invasive neuroimaging techniques, showcasing great progress particularly in MRI imaging of white
34 matter connectivity (Van Essen et al. 2013; Setsompop et al. 2013). Concurrently to the progress in white
35 matter imaging through MRI, promising strides have also been made in imaging of the laminar
36 composition of cortical grey matter. The progress in imaging the substructure of cortical grey matter
37 began with establishing that myelination causes shortening of T1 values (Clark et al. 1992). Next, T1
38 values were linked to myeloarchitecture (Barbier et al. 2002; Duyn et al. 2007; Van Essen et al. 2019),
39 and the correspondence between T1 clusters and cortical layers was established in rat brains (Barazany
40 and Assaf 2012). Subsequent studies have shown that low resolution T1 MRI can also be used to provide
41 information regarding cortical layers in the human brain (Glasser et al. 2014; Shafee et al. 2015; Lifshits
42 et al. 2018). A complete methodological framework was then established for MRI-based quantification
43 and visualization of the cortical laminar composition (Shamir et al. 2019).

44 Despite growing progress in connectomics, starting from the macroscale and progressing gradually into
45 higher resolutions in meso- and microscales, the field remains inherently limited by the biased
46 representation of the cortex as a single homogenous unit. Due to the current scarcity of information
47 regarding laminar end points of white matter tracts inside the cortical grey matter, tractography remains
48 focused on transverse partitioning of the cortex into regions, while ignoring radial partitioning into
49 laminar components (Jbabdi and Johansen-Berg 2011).

50 The integration of macrostructural data regarding white matter connectomics and microstructural data
51 regarding grey matter laminar composition poses a promising development in the field of connectomics
52 (Johansen-Berg 2013). A recently published study offers a simplified granularity-based model of cortical
53 laminar connectivity based on published tract tracing and histological findings, with the purpose of

Modelling the laminar connectome of the human brain

54 integrating white and grey matter datasets derived from multimodal MRI imaging (Shamir and Assaf,
55 2021a). The model is then further explored in the macaque brain and corroborated in its visual cortex by
56 comparison to published studies (Shamir and Assaf 2021b). The resulting micro-level connectome offers
57 a more detailed and unbiased representation of the connectome and offers new prospects in the field of
58 both structural and functional connectivity on the laminar level.

59 In this study we model the laminar connectome of the healthy human brain (N=30 healthy subjects) and
60 explore it via a set of neurobiologically meaningful complex network measures. We focus on
61 investigating network hubs in the standard cortical connectome versus those in the cortical laminar
62 connectome.

63 **Methods and materials**

64 The framework for modelling cortical laminar connectivity (Shamir and Assaf 2021a) was applied on a
65 set of (N=30) healthy human subjects.

66 **Subjects**

67 Thirty healthy human subjects (N=30), including 14 male and 16 female, 18-78 years old. Subjects were
68 neurologically and radiologically healthy with no history of neurological diseases. The imaging protocol
69 was approved by the institutional review boards of Sheba Medical Center and Tel Aviv University, where
70 the MRI investigations were performed. All subjects signed informed consent before enrollment in the
71 study.

72 Each subject was scanned on a 3T Magnetom Siemens Prisma (Siemens, Erlangen, Germany) scanner
73 with a 64-channel RF coil. The scans include the following sequences:

- 74 1. A standard diffusion-weighted imaging (DWI) sequence, with the following parameters:
75 $\Delta/\delta=60/15.5$ ms, $b \text{ max}=5000$ (0 250 1000 3000 & 5000) s/mm^2 , with 87 gradient directions, FoV
76 204 mm, $\text{maxG}= 7.2$, $\text{TR}=5200$ ms, $\text{TE}=118$ ms, $1.5 \times 1.5 \times 1.5 \text{ mm}^3$, $128 \times 128 \times 94$ voxels. This
77 sequence was used for mapping the cortical connectome.
- 78 2. An MPRAGE sequence, with the following parameters: $\text{TR/TE} = 1750/2.6$ ms, $\text{TI} = 900$ ms, $1 \times 1 \times 1$
79 mm^3 , $224 \times 224 \times 160$ voxels, each voxel fitted with a single T1 value. This sequence was used for
80 delineating the cortical surfaces.

Modelling the laminar connectome of the human brain

81 3. An inversion recovery echo planar imaging (IR EPI) sequence, with the following parameters:
82 TR/TE = 10,000/30 ms and 60 inversion times spread between 50 ms up to 3,000 ms, $3 \times 3 \times 3$ mm³,
83 $68 \times 68 \times 42$ voxels, each voxel fitted with up to 7 T1 values (Lifshits et al. 2018). This sequence used
84 for characterizing the cortical layers.

85 **Image processing**

86 The following datasets were analyzed across Brainnetome atlas regions, a connectivity-based
87 parcellation which consists of 210 cortical regions and 36 subcortical subregions (Fan et al. 2016):

88 1. **Global white matter connectivity analysis**

89 Each DWI dataset was analyzed for global white matter connectivity using global tractography.
90 Traditional tractography involves streamline estimation by inferring connectivity from local
91 orientation fields. It has been proven that streamline estimation experiences difficulties in
92 reconstructing long tracts, due to high false positive rates associated with strong tracts, alongside
93 difficulties reconstructing complex geometries, due to the partial volume effect associated with
94 crossing fibers (Maier-Hein et al. 2017).

95 Global tractography differs from streamline tracking conceptually and methodologically by
96 finding the full track configuration that best explains the measured DWI data. As a result, this
97 tractography method is less sensitive to noise, and the density of the resulting tractogram is more
98 directly related to the data. The analysis was conducted using MRtrix3 software package, which
99 uses a multi-tissue spherical convolution model that accounts for partial volumes (Tournier et al.
100 2019), similarly to the analysis by Krupnik et al. (2021).

101 For a visualization of the resulting connectivity matrix of the 30-subject average, see figure 1a
102 (below).

103 2. **Cortical laminar composition analysis**

104 Each IR EPI dataset and its corresponding MPRAGE were analyzed for cortical laminar
105 composition using our original framework, according to the following four principal steps:

106 a. *IR decay function fit*: the low resolution fast echo planar imaging inversion recovery (EPI IR)
107 protocol was utilized for estimation of multiple T1 components per voxel using the following
108 IR decay function fit (Lifshits et al. 2018):

Modelling the laminar connectome of the human brain

109
$$M(TI_i) = \sum_{j=1}^7 M0_j \cdot (1 - 2e^{-TI_i/T_{1j}})$$
 (1)

110 Where:

111 $M(TI_i)$ - Magnetization at the i^{th} inversion recovery image, in other words the magnetization
112 measured for each specific T1 component

113 $M0_j$ - Predicted magnetization at $TI=0$ ms for each T1 component (j) in the voxel

114 T_{1j} - Longitudinal relaxation time for each T1 component

115 j was set up to 7 for the low resolution experiments, indicating fit to seven individual
116 exponential fits, based on the assumption that there are 7 T1 components in the tissue – 1 for
117 CSF, 1 for WM and heavily myelinated layer of the cortex and additional 5 cortical layers.

118 Normalization of each of the predicted magnetization values according to $\frac{M0_j}{\sum_{i=1}^j M0_j}$ then
119 represents the voxel contribution of each corresponding T1 component (j).

120 b. *T1 probabilistic classification*: T1 values were then assigned to different brain tissues and
121 utilized to extract the subvoxel composition of each T1 layer (Lifshits et al. 2018; Barazany
122 and Assaf 2012; Peel et al. 2000; Shamir et al. 2019; Lotan et al. 2021). The T1 classification
123 process involved fitting the T1 histogram to a probabilistic mixture model consisting of t-
124 distributions. The probability of each t-distribution in the voxel was calculated according
125 Bayes' formula:

126
$$P_k = \sum_{i=1}^7 f_i \cdot \frac{p(T_{1(i)}|k)p(k)}{p(T_{1(i)})}$$
 (2)

127 Where:

128 k - A specific t-distribution

129 $T_{1(i)}$ - T1-value of the i^{th} component of the voxel

130 f_i - Partial volume of $T_{1(i)}$ (normalized as show in previous section)

131 $p(T_1)$ - General whole-brain probability of a T_1 -value

132 $p(k)$ - Probability of t-distribution k

133 $p(T_1|k)$ - Probability of the T_1 -value in t-distribution k

134 Fit to 18 t-distributions was deemed satisfactory according to evaluation of the Bayesian
135 information criterion for 1-20 t-distributions. Each resulting group of distributions then
136 corresponds to various types of brain tissue:

137 i. White matter (WM) characterized by low T1 values, represented by t-distribution 1-3.

Modelling the laminar connectome of the human brain

- 138 ii. Gray matter (GM) characterized by mid-range T1 values, represented by t-distributions 4-
139 9, corresponding to 6 T1 layers. Since T1 is considered a measure of myelination (Clark
140 et al. 1992), T1 layers with higher indices (or smaller T1 values), are more myelinated and
141 are therefore located deeper in the cortical cross section. t-distributions 4,5,6,7,8, and 9 are
142 then termed T1 layers 6,5,4,3,2 and 1 (respectively).
- 143 iii. Cerebral spinal fluid (CSF) characterized by high T1 values, represented by t-distributions
144 10-18.
- 145 c. *Cortical volume sampling*: We then implemented a geometric solution to cortical sampling
146 based on a system of virtual spheres dispersed throughout the entire cortex. A sphere was
147 chosen as a robust alternative to cortical normals due to its symmetry and invariance to rotation
148 (Shamir et al. 2019). The sampling process started with delineation of the inner, mid, and outer
149 cortical surfaces using the *FreeSurfer* pipeline (Fischl 2012). The virtual spheres were then
150 generated with centers on the mid surface and edges tangential to both the inner and outer
151 cortical surfaces. Each hemispheric volume consists of ~75,000 spherical volumes with an
152 average radius of ~1 mm.
- 153 d. *Data sampling*: To sample the high resolution spheres in the low resolution T1 dataset
154 (3^3 mm^3), a super-resolution solution was implemented. The solution involved partitioning
155 each voxel into 10^3 subvoxels, each assigned location properties, primarily their location
156 inside or outside of a given sphere. Spherical volume weights were then assigned to each
157 sphere, corresponding to each voxel's contribution to its spherical volume, according to the
158 following:

$$159 \quad W_{\text{voxel}_i, \text{sphere}_j} = \frac{N_{\text{voxel}_i, \text{sphere}_j}}{N_{\text{sphere}_j}} \quad (3)$$

160 Where:

161 $W_{\text{voxel}_i, \text{sphere}_j}$ - Volume weight of voxel i per sphere j

162 $N_{\text{voxel}_i, \text{sphere}_j}$ - Number of subvoxels from voxel i located inside sphere j

163 N_{sphere_j} - Total number of subvoxels located inside sphere j

164 The cortical composition of each sphere was then estimated by multiplying the volume
165 weights of each sphere by their corresponding voxel probability maps (see *T1 probabilistic*

Modelling the laminar connectome of the human brain

166 *classification*). The process was repeated across all spheres, according to the following
167 equation:

$$168 \quad P(t_k/\text{sphere}) = \sum_{i=1}^M \sum_{k=2}^7 W_{\text{voxel}_i, \text{sphere}_j} \cdot P(t_k/\text{voxel}_i) \quad (4)$$

169 Where:

170 $P(t_k/\text{sphere})$ - Probability of t-distribution k per sphere

171 k- t-distributions 4,5,...,9, representing T1 layers 6,5,...,1 (respectively)

172 M- Number of voxels within which sphere j lies

173 $W_{\text{voxel}_i, \text{sphere}_j}$ - Volume weight of voxel i per sphere j

174 $P(t_k/\text{voxel}_i)$ - Probability of t-distribution k in voxel i

175 The resulting whole-brain cortical laminar composition is then simplified by grouping the
176 layers into three laminar components:

- 177 i. Supragranular (SG) laminar component, which includes T1 layers 1, 2, and 3.
- 178 ii. Granular (G) laminar component, which includes granular T1 layer 4.
- 179 iii. Infragranular (IG) component, which includes T1 layers 5 and 6.

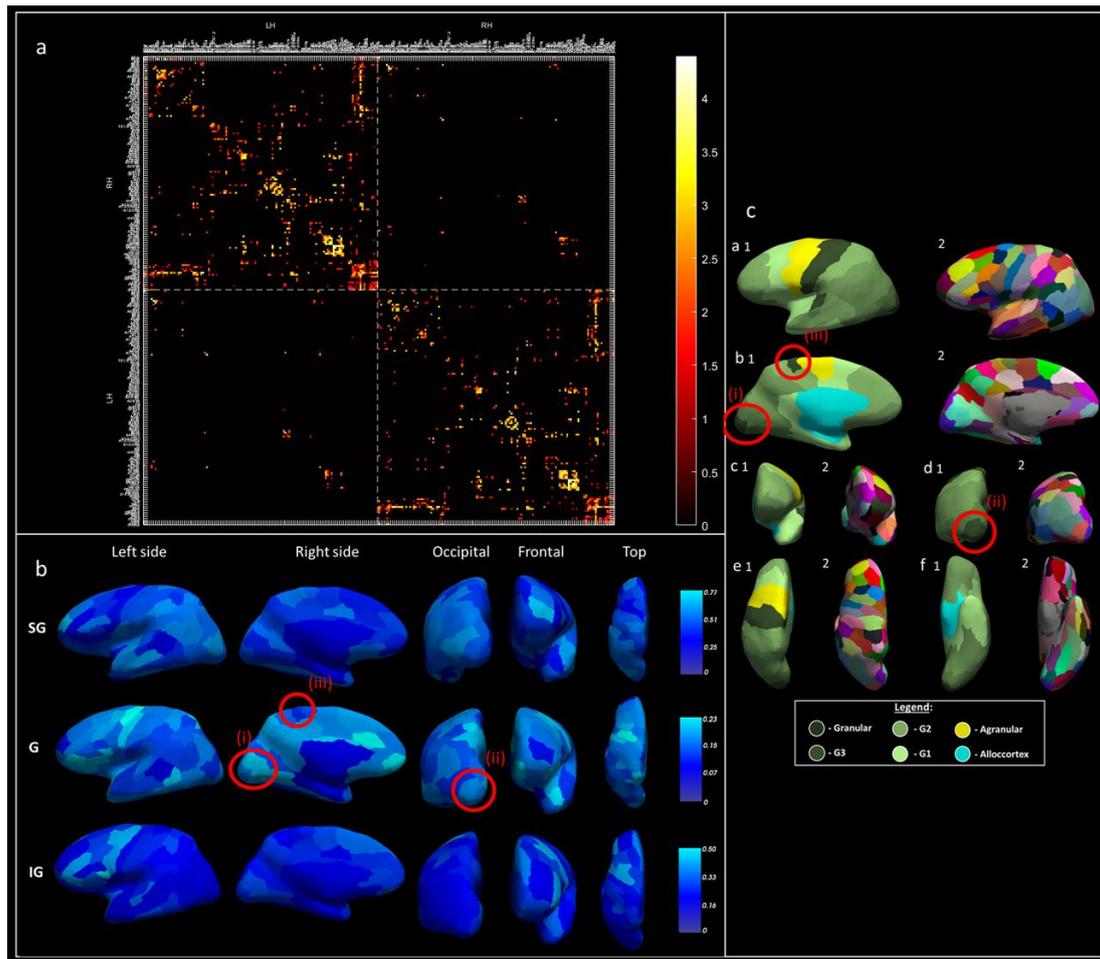

180 For a visualization of the resulting cortical laminar composition of the three laminar components,
181 averaged across all 30 subjects, see figure 1b (below).

182 3. **Model of cortical laminar connectivity**

183 The multimodal MRI datasets were integrated using the data-derived, granularity-based model of
184 cortical laminar connectivity (Shamir and Assaf 2021a, b). The model includes a set of whole-
185 brain laminar-level connectivity rules that integrate white matter connectomics on a macroscale
186 and grey matter composition on a mesoscale, using a set of granularity-based connectivity rules.
187 To implement the model rules, each region in the Brainnetome atlas was labelled according to its
188 granularity index (see figure 1c below). The labelling process was conducted manually according
189 to an adapted von Economo- Koskinas atlas (Solari and Stoner 2011; Beul and Hilgetag 2015),
190 and similarly to the labelling by Shamir and Assaf (2021a).

191 Each Brainnetome atlas region then holds three components, corresponding to its white matter
192 connections, its grey matter laminar composition, and its granularity index. These components are
193 crucial for the model application, since its rules use weighting of white matter tracts according to

Fig. 1 Average global white and gray matter datasets and estimated granularity indices across

Brainnetome atlas regions:

- a- Average cortical connectivity (of all 30 subjects) across left (LH) and right (RH) hemispheres: average connectivity matrix, representing (log(number of tracts)) for connections that appear in at least 75% of subjects (color scheme adapted from Charles 2021)
 - b- Average cortical laminar composition (of all 30 subjects) across left hemisphere: where: top row- supragranular layers (SG), middle row- granular layer (G), bottom row- infragranular layers (IG), and columns represent different viewpoints
 - c- Granularity indices (left- 1) and Brainnetome atlas regions (right- 2) across left hemisphere, from several viewpoints: left side (a), right side (B), front (C), occipital (D), top (E), and bottom (F)
- Features in b and their respective counterparts in c correspond to unique granular presence (circled in red): features (i) and (ii): high presence of granular laminar component in V1 (in b), in correspondence with a high granularity index (in c); feature (iii): low presence of granular laminar component in M1 (in b), in correspondence with a low granularity index (in c)

Modelling the laminar connectome of the human brain

224 the cortical laminar compositions of the connecting regions based on their respective granularity
225 indices. The model then addresses two types of cortical connections:

226 a. *Tractography-based (long-range) connections*: tractography-based connections represent
227 most of the connections in the model, including relatively stronger connections between
228 different cortical regions, as well as connections between the cortex and the subcortex. They
229 are expanded to the laminar level according to the rule of connectivity that corresponds to the
230 connecting regions, their granularity indices, and their laminar compositions.

231 b. *Assumed (short-range) connections*: assumed connections include vertically-oriented
232 connections between different laminar components within a single cortical region. They are
233 modelled as relatively weaker connections in the model according to the laminar composition
234 of each cortical region.

235 For a comprehensive description of the model of cortical laminar connectivity and its data-derived origin,
236 see (Shamir and Assaf 2021a). The resulting laminar connectome includes three times as many nodes as
237 the standard connectome since each original regional node now consists of three laminar locations in that
238 same specific region. A full visualization of the 30-subject average of the resulting model of laminar
239 connectivity can be seen in figure 2 parts a-b (below). The source code of the average standard and
240 laminar connectomes, as well as the complete code for modelling a laminar-level connectome, are freely
241 available for noncommercial use (at github.com/ittais/Laminar_Connectivity).

242 The variability of the resulting connectomes, representing both standard connectivity and laminar
243 connectivity across subjects (N=30), are then evaluated (see figure 2 parts b-c). Subsequently, both
244 connectomes are then explored via a set of neurobiologically meaningful complex network measures
245 (Rubinov and Sporns 2010).

246 4. **Complex network analysis**

247 Once the standard connectome was extracted and the laminar connectome was modelled, we used tools
248 for network analysis to explore their connectivity patterns and unique network features:

249 a. **Network complexity**: both connectomes were initially tested for non-trivial topological features
250 that occur in complex networks, such as a heavy tail in degree distribution, but do not occur in
251 simple networks, such as random graphs (see figure 3 below).

275

276

b. **Network analysis:** once the complexity of both networks was shown, we explored and compared the average standard connectome to the components of the average laminar connectome. Global connectivity measures, including global efficiency and connectivity density, were chosen for evaluating the cost-efficiency trade-off. Additionally, local connectivity measures of centrality were calculated, including node degree and strength.

295 Distributions of degrees for both the standard cortical connectome (a), as well as the cortical laminar

296 connectome (b1), of the average connectomes for all connections that appear in at least 75% of subjects.

297 Each of the two is presented against a random network with an equal number of nodes and edges

298 (histogram outlines in green). For the laminar connectome, distributions for each laminar connectome

299 are colored individually (b2): infragranular (IG)- red, granular (G)- green, supragranular (SG)- blue

300 Notice the positive skew, or “heavy-tail”, in degree distributions in both cases and expressly in the

301 laminar connectome

302 For a schematic representation of our methodology for modelling and analyzing the laminar connectome,

303 see Supplementary Material figure 1.

304 Results

305 After calculating average matrices for both standard cortical and cortical laminar connectomes, the

306 variability of both connectomes was evaluated across all N=30 subjects (see figure 2 parts c-d). The

307 standard connectome exhibits relatively higher standard deviation values, that correspond to the overall

308 higher range of connectivity values. The subcortocortical connections exhibit relatively higher standard

309 deviation within each matrix, specifically in the granular to granular connections for the laminar

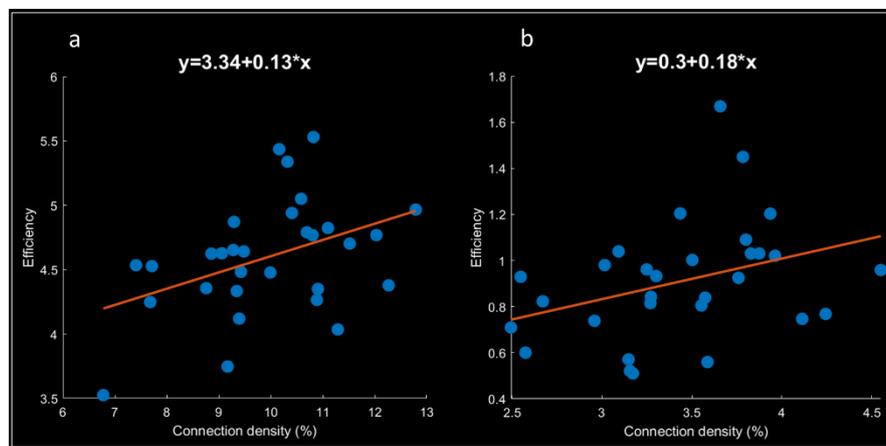

Modelling the laminar connectome of the human brain

310 connectome. This can be attributed to the higher connection values of subcortocortical connections,
311 relative to corticocortical connections.

312 Two measures of global network connectivity were calculated for both the average standard and average
313 laminar connectomes:

- 314 1. Global efficiency- an efficiency measure representing the average inverse shortest path length in
315 the network.
- 316 2. Connection density- a cost measure representing the number of edges in a network as a proportion
317 of the maximum possible number of edges.

318 The two measures were then plotted against one another to evaluate the cost-efficiency trade-off
319 (Bullmore and Sporns 2012) in both connectomes (see figure 4).

327 **Fig. 4** Cost-efficiency trade-offs of both connectomes:

328 Global efficiency and connection density values, fitted to a linear regression model (top), for all N=30
329 subjects, including the standard cortical connectomes (a) and the cortical laminar connectomes (b)

330 Examination of the cost-efficiency trade-off in the cortical laminar connectome shows that both the
331 connection density as well as the global efficiency are reduced compared to the standard connectome.

332 Connection density is a value inversely related to the maximum possible number of edges in the standard

333 connectome: $Max_{edges\ standard} = \frac{N^2 - N}{2}$, where N is the number of nodes in the standard connectome

334 network. The number of nodes in the laminar connectome is $3 * N$, since the cortex is divided into three

335 cortical components. Accordingly, the maximum possible number of edges in the laminar connectome

336 for big networks (large enough N): $Max_{edges\ laminar} \sim 9 * Max_{edges\ standard}$. Since the density is

337 inversely related to the maximum possible number of edges, theoretically the ratio should be:

338 $Density_{laminar} \sim \frac{1}{9} * Density_{standard}$. In practice, the laminar connectome exhibits higher density than

Modelling the laminar connectome of the human brain

339 expected that instead follows: $Density_{laminar} \sim \frac{1}{3} * Density_{standard}$ (see density value range in figure
340 4). Global efficiency is a value inversely related to the mean shortest path (MSP), where:
341 $MSP_{standard} \propto N$. Since the laminar connectome has $3 * N$ nodes, the efficiency of the laminar
342 connectome should follow: $Efficiency_{laminar} \sim \frac{1}{3} * Efficiency_{standard}$. In this case, the laminar
343 connectome does roughly follow this ratio (see efficiency range in figure 4). Consequently, the efficiency
344 to density ratio for the laminar connectome is slightly higher than for the standard connectome.

345 To examine the connectivity patterns of both the standard connectome as well as the cortical laminar
346 connectome, we conducted an analysis of a two neurobiologically meaningful network measures
347 (Rubinov and Sporns 2010). The following two measures of centrality were included:

- 348 1. Degree- the number of edges connected to a node (see figure 5, below).
- 349 2. Strength- sum of all neighboring edge weights (see figure 6, below)

350 For an exploration of additional measures, including clustering coefficient, local efficiency, and
351 core/periphery, see Supplementary Material figure 2.

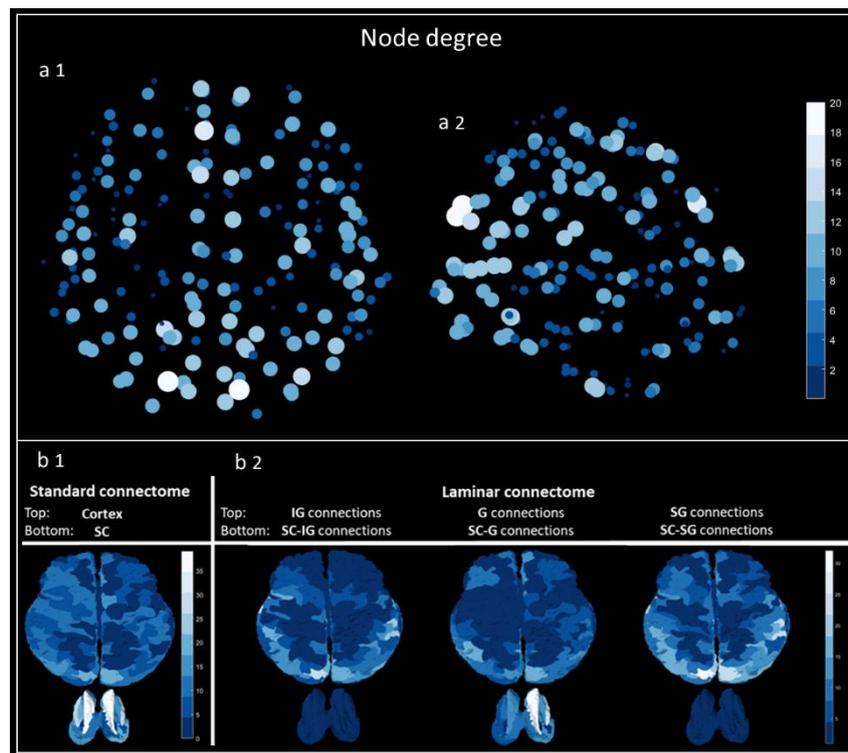

Fig. 5 Node degree:

363 a- Distribution of degree values for the average standard connectome across cortical regions of the
364 Brainnetome atlas, top view (a1) and lateral view (a2)

Modelling the laminar connectome of the human brain

365 b- Whole-brain distributions of degree values for the average standard connectome (left column)
366 compared to the average laminar connectome, including: infragranular (IG), granular (G) and
367 supragranular (SG) components (3 right columns, left to right). Each connectome depicts cortical
368 connections (top) and subcortical connections (bottom). For each laminar component, cortical
369 connections include connections between the specified component and all other components (top),
370 and subcortical connections include connections between the specified component and the
371 subcortex (bottom)

372 When examining the degree values across cortical regions of the standard connectome, a well-established
373 pattern of node centrality appears in the occipital, temporal, and medial parietal cortices (Sporns 2009).
374 When examining the degrees across both connectomes, subcortical regions (thalamus, caudate, putamen
375 and hippocampus) alongside a set of cortical regions appear as hubs with high degree values, including:
376 superior frontal regions (A9m, A10m), superior parietal regions (A7 subregions), superior occipital
377 regions (msOccG) and the cuneus (rCunG). These hubs exhibit both high degree and high strength in the
378 standard connectome, as well as cumulatively across components of the laminar connectome. The
379 infragranular and supragranular components do not include the subcortex but include cortical hubs, while
380 the granular component includes the subcortex and mainly non-frontal hubs such superior parietal and
381 superior occipital regions.

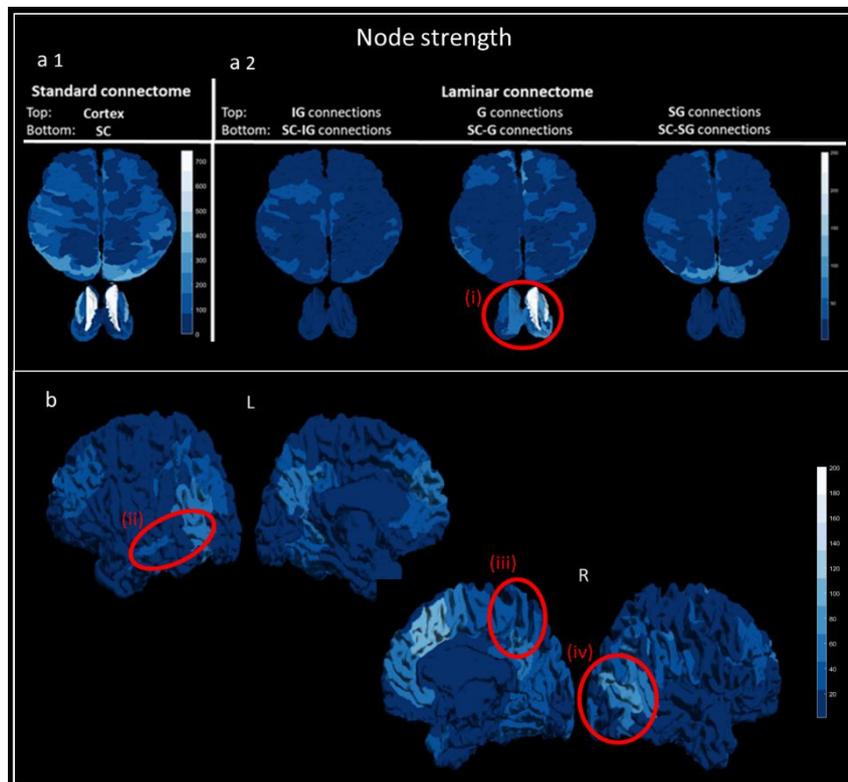

Fig. 6 Node strength:

Modelling the laminar connectome of the human brain

395 a- Whole-brain distributions of strength values for the average standard connectome (left column)
396 compared to the average laminar connectome, including: infragranular (IG), granular (G) and
397 supragranular (SG) components (3 right columns, left to right). Each connectome depicts cortical
398 connections (top) and subcortical connections (bottom). For each laminar component, cortical
399 connections include connections between the specified component and all other components (top),
400 and subcortical connections include connections between the specified component and the
401 subcortex (bottom). Feature (i) (circled in red) shows high centrality of subcortical regions for the
402 granular component of the laminar connectome

403 b- Distribution of strength values for the granular (G) component of the laminar connectome across
404 both left (L, top) and right (R, bottom) hemispheres, from lateral view (left) and sagittal view (right).
405 Features (circled in red) show high strength values in the auditory cortex (ii), as well as the primary
406 motor (iii) and primary visual (iv) cortices

407 When examining the strength (weighted degree) values, a similar more generalized pattern appears. In
408 the standard connectome, the subcortex overpowers the distribution across nodes and exhibits the highest
409 strength values, followed by occipital and parietal regions. In the laminar connectome, the granular
410 component exhibits high strength values in the subcortex. A closer examination of the granular
411 component demonstrates high strength values in the auditory cortex, alongside the primary motor and
412 primary visual cortices.

413 **Discussion**

414 In this study we model and explore the laminar connectome of N=30 healthy subjects using multimodal
415 MRI imaging datasets. These datasets include both white matter connectivity and grey matter laminar
416 composition, which are integrated using our novel model of cortical laminar connectivity (Shamir and
417 Assaf 2021a, b). The resulting laminar-level connectome is then explored across the Brainnetome atlas
418 regions (Fan et al. 2016) using a set of neurobiologically meaningful complex network measures
419 (Rubinov and Sporns 2010), while focusing on comparison of the cortical laminar connectome to
420 standard cortical connectome.

421 When we examine both connectomes on a global scale, several similarities and other differences appear.

422 On the similarity side, both connectomes exhibit a heavy tail in their degree distributions, which is even

Modelling the laminar connectome of the human brain

423 more noticeable in the laminar connectome. A heavy tail in a degree distribution is a non-trivial
424 topological feature that occurs in complex networks but does not occur in simple or random networks.
425 This feature is also associated with higher network resilience to nodal removal (regional damage). On
426 the difference side, the standard connectome exhibits relatively higher standard deviation values across
427 subjects, relative to the laminar connectome. This higher variability corresponds to the overall higher
428 range of connectivity values in the standard connectome. Nonetheless, both connectomes exhibit higher
429 variability in subcortical connections, which can once again be attributed to stronger connections
430 relative to corticocortical connections. An additional difference between the two connectomes appears
431 when exploring the cost-efficiency trade-offs, by plotting global efficiency against connection density.
432 The laminar connectome exhibits higher connection density than expected based on the relative number
433 of nodes in the network alone. With regards to efficiency, the laminar connectome exhibits a relatively
434 lower global efficiency, as expected based on number of nodes alone. However, the efficiency to density
435 ratio is maintained and even slightly elevated for the laminar connectome in comparison to the standard
436 connectome.

437 When we examine both connectomes on a local scale using complex network measures, we get a more
438 nuanced image of connectivity patterns across the brain. Several features appear in the granular
439 component of the laminar connectome, including high subcortical centrality on a whole-brain level,
440 alongside high regional centrality in the auditory cortex, M1, and V1 on a cortical level. In addition, the
441 distributions of degree and strength values in the standard connectome reestablish the notion of a rich-
442 club bihemispheric organization that includes subcortical regions (van den Heuvel and Sporns 2011,
443 2013). The distribution of these values across components of the laminar connectome exhibits a
444 cumulative nature, which is strengthened upon further examination of the core/periphery partitioning in
445 the standard connectome (for an examination of inter-subject consistency, see Supplementary Material
446 figure 3). The standard connectome displays a core of highly interconnected hubs across the cortex and
447 subcortex, a subset of these hubs appears in each individual component of the laminar connectome. The
448 infragranular component displays hubs across non-frontal cortical regions, the granular component
449 displays hubs that include subcortical regions, and the supragranular component displays hubs that
450 include frontal cortical regions.

Modelling the laminar connectome of the human brain

451 This study presents an innovative exploration of a network model of the healthy human connectome on
452 the laminar level. This model embodies a simplified set of laminar-level rules of connections, based on
453 a systematic review of histological tract tracing studies (Shamir and Assaf 2021a). While this model has
454 been corroborated ex-vivo in the macaque brain (Felleman and Van Essen 1991; Shamir and Assaf
455 2021b), corroborating the results in-vivo in the human brain is a more nuanced task. However, our
456 network analysis showcases several expected features, mainly concerning high centrality of granular
457 connections to visual, motor, and auditory regions.

458 The characterization of the healthy human laminar connectome presented here could support the
459 investigating of pathologies that are assumed to involve abnormalities in layer-dependent cortical
460 connectivity, such as schizophrenia and autism. Using the network modelling and analysis framework
461 presented here, the patterns of connectivity behind such conditions could be further explored and
462 elucidated.
