Abstract

Background

Non-pharmaceutical intervention (NPI) remains the most reliable COVID-19 containment tool for low- and middle-income countries (LMICs) given the inequality of vaccine distribution and their vulnerable healthcare systems. We aimed to develop mathematical models that capture LMIC demographic characteristics such as young population and large household size and assess NPI effectiveness in rural and urban communities.

Methods

We constructed synthetic populations for rural, non-slum urban and slum settings to capture LMIC demographic characteristics that vary across communities. We integrated age mixing and household structure into contact networks for each community setting and simulated COVID-19 outbreaks within the networks. Using this agent-based model, we evaluate NPIs including testing and isolation, tracing and quarantine, and physical distancing. We explored the optimal containment strategies for rural and urban communities by designing and simulating setting-specific strategies that deploy rapid diagnostic test, symptom screening, contact tracing and physical distancing. We performed extensive simulations to capture the uncertainty of outbreak trajectories and the impact of varying model parameters.

Findings

We found the impact of testing, tracing and distancing varies with rural-urban settings. In rural communities, we found implementing either high quality (sensitivity > 50%) antigen rapid diagnostic tests or moderate physical distancing could contain the transmission. Additionally, antibody rapid diagnostic tests and symptom-based diagnosis could be useful for mitigating the transmission. In non-slum urban communities, we demonstrated that both physical distancing and case finding are essential for containing COVID-19 (average infection rate < 10%). In slum communities, we found physical distancing is less effective compared to rural and non-slum urban communities. Lastly, for all communities considered, we demonstrated contact quarantine is essential for effective containment and is effective at a low compliance rate (30%).

Interpretation

Our findings could guide setting-specific strategy design for different communities in LMICs. Our assessments also have implications on applying rapid diagnostic tests and symptom-based diagnosis for case finding, tracing and distancing in lower-income communities.

Introduction

The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), which causes the COVID-19, has rapidly spread worldwide since the end of 2019. (Zhu et al., 2020) Without effective pharmaceutical interventions (e.g., vaccines), many low- and middle- income countries (LMICs) rely on non-pharmaceutical interventions (NPIs) to control COVID-19, (Brauner et al., 2021; J. N. Nkengasong et al., 2020) such as physical distancing, travel restriction, and testing and tracing programs. While contributing to COVID-19 control, these NPIs may cause considerable damage to the economies as people put their life and work on hold. (Hodgins & Saad, 2020) Therefore, evaluating the effectiveness of NPIs could inform government decisions and ease the burden on the economy and society. (Brauner et al., 2021)

Many COVID-19 containment policies rely on testing which can be challenging to implement in LMIC because of the limited clinical resources (Bong et al., 2020; Murthy et al., 2015) and laboratory capacities. (Hasell et al., 2020; J. Nkengasong, 2020) Specifically, the real-time reverse transcription-polymerase chain reaction (RT-PCR), the most common tool for detecting SARS-CoV-2, requires lab facilities that are insufficient in LMICs. (Corman et al., 2020; Shen et al., 2020) These limitations pose challenges for early detection of SARS-CoV-2 transmission, which is crucial to LMICs due to their vulnerable healthcare systems. Therefore, it is essential to leverage alternative testing methods, such as rapid diagnostic tests (RDT) based on antigen or host antibody detection (Jacobs et al., 2020; Krueger et al., 2020; Organization & Others, 2020; Porte et al., 2020) which is less resource-demanding. Additionally, community healthcare workers could perform contact tracing and quarantine to further mitigate the SARS-CoV-2 transmission, which has been implemented successfully during HIV and Tuberculosis outbreaks. (Shapiro et al., 2012) Combining RDT, contact tracing and quarantine, we can increase the testing capacity, ensure early and accurate detection of infected cases, and to contain disease transmission and avoid complete lockdown.

In this study, we evaluated the dynamics of COVID-19 transmission in younger populations that are typical of LMICs and the effectiveness of testing, tracing and distancing. We constructed an

agent-based model using synthetic contact networks that reflect the demographic structures in lower-income communities. To account for the different infection rates across geographical locations, (Baqui et al., 2020; El-Sadr & Justman, 2020), we simulated SARS-CoV-2 transmission in the rural, non-slum urban and slum settings of LMICs and captured the uncertainty of the epidemic sizes by replicating the simulation with bootstrap samples of contact networks. For each setting, we evaluated the impact of various testing methods with or without physical distancing on COVID-19 transmission. Our simulation results suggest combined strategies of testing, close contact tracing and moderate physical distancing could reduce the number of infections significantly. We also showed that RDT and symptom-based diagnosis could be deployed in several settings for better containment outcomes.

Material and methods

Processing demographic data

We cited the age distribution and household sizes from the United nation. (Department of Economic and Social Affairs, 2020; United Nation, 2017) (Supplementary Table 1) We considered three age groups (0-14, 15-25 and 25+ years old) for simplicity and to capture the susceptibility of the younger population and contact structure differences between younger and older groups. We cited the contact survey data from a study in Uganda to compute age-specific contact matrices, contact numbers, and contact distribution within households (le Polain de Waroux et al., 2018). To compare the model using different demographic data, we included projected contact matrices from Kenya, South Africa and Nigeria. (Prem et al., 2017) We chose Kenya and South Africa as their projected data were compared with empirical data in the cited study; we chose Nigeria as it is located in Western Africa and has a large population. When using the contact matrices in simulation, we scaled the contact matrix to match the average daily contact number under each community setting. (Table 1)

Agent-based modelling

We used an agent-based model and configured the communities based on the age distributions and household sizes in South Africa, Kenya, Nigeria, and Uganda. We modelled three different

community settings for LMICs: non-slum urban areas, rural areas, and slums, which differ in parameters including household sizes, daily close contact numbers, and percentage of contact between members from the same household. (Food and Agriculture Organization, 2018) (Table 1) For each community setting, we simulated 20 synthetic populations, where each household composed of at least one adult above age 25, and each household was assigned to a location on a two-dimensional plane. The contact networks for the synthetic population were configured for the corresponding household structure, age-specific contact matrices, and geographical clustering, using an Exponential Random Graph Model (ERGM). (Robins et al., 2007) See Supplemental Methods for details on the ERGM.

After constructing the synthetic populations with contact and household structure, we randomly choose one of the 20 synthetic populations and simulated COVID-19 transmission initiated by importing 2 cases. At each time step of a simulated outbreak, one realized contact network of ERGM was sampled to represent the daily dynamic of contacts. (Figure 1) Infection events were sampled among the contacts proportional to the transmissibility multiplied by generation time, which is a Weibull distribution that has a mode on the day of onset. (Sun et al., 2020) The day of onset for each infected individual was sampled from the cited incubation time distribution (Ferretti et al., 2020). The susceptibility of the younger group (0-14 years old) was set to 50% of that of the older group (15+ years old). (Davies et al., 2020; Zhang et al., 2020) Using the age-dependent susceptibility and basic reproduction number, we computed the next generation matrix and the transmissibility. (Supplementary Methods) At each infection event, we sampled whether an infected individual is asymptomatic using a Bernoulli distribution of probability equal to 30%. (Table 1) For detailed parameterization of transmission dynamics, see Supplementary Methods.

We tested our model from two perspectives. Firstly, we tested if our model reflects the cited contact data and transmission dynamics by comparing the simulated contact distribution and generation time with the empirical data. (Figure 2) Secondly, we tested if the cited generation time and incubation time capture the temporal dynamics of transmission by comparing the

growth curve in our simulation to those of the UK (March 10th to March 24th) and China (January 9th to January 23rd) (Z. Wu & McGoogan, 2020) before lockdown. We assumed no major behavioural change in the populations and constant case discovery rates within the selected time interval for these two countries. Moreover, we compared the averaged outbreak trajectories of the four countries simulated, and proceeded with synthetic populations of Uganda, because no obvious deviation was observed (Supplementary Figure 1).

NPI simulation

We evaluated the impact of testing alone and in combination with other NPIs, which include contact tracing, quarantine, and physical distancing, for LMICs. (Figure 1B) The testing methods considered were PCR, antigen RDT and antibody RDT. We simulated that only individuals with symptoms and agree to be tested will receive testing. In our simulation, an infected individual with symptoms will be discovered at a rate which is the product of four parameters: healthcare seeking rate, test consent rate, sampling success rate and lab sensitivity of the test. Values and sources of testing parameters were summarised in Table 2.

Our simulation assumes a test is always performed with close contact tracing and quarantine, unless specified otherwise. We assumed only close contacts of confirmed cases who consent to be isolated will be tracked. Therefore, the overall quarantine rate is determined by the product of three parameters: isolation consent rate of the infector, tracing success rate (we assumed a tracing success rate equal to 100% for members within the same household of the infector) and quarantine consent rate of the contacts. Physical distancing was modelled by reducing the number of contacts outside the households. We simulated the effect of physical distancing by reducing the out-of-household contact number by 20% to 80% with 20% increments. We approximate the effective reproduction number Re under physical distancing by scaling Re proportionally to the average daily contact numbers.

To identify the effective NPIs for LMICs, we simulated combined testing strategies. The strategies evaluated included 1) a symptom-based quarantine with low compliance rate

performed with PCR testing, 2) a symptom-based quarantine with low compliance rate performed with PCR testing and antibody RDT, 3) and antigen RDT in combination with PCR testing. (Supplementary Table 2) The availability of PCR testing is assumed to be affluent for non-slum urban areas, limited for slums and not available for rural areas. All three strategies were replicated with and without physical distancing for 200 outbreak trajectories to estimate the average daily incidence number. We simulated each trajectory for 100 days to guarantee that the transmission extincts within the synthetic population.

Sensitivity analysis

We performed the sensitivity analysis separately for baseline conditions and for intervened conditions. For the baseline conditions, we simulated outbreaks over grids of values for transmission and demographic variables that are assumed or could not be determined from literature. We computed R^2 using the total infected number as the dependent variable to capture the proportion of variance explained by each variable. (Table 1). For the intervened conditions, we performed the same simulations over grids of values for testing and NPI variables. We computed the R^2 using infected numbers under three different intervention strategies as the dependent variables and testing/NPI variables in Supplementary table 3 as independent variables. In total we have 2,028 simulation settings (3 community settings, 4 containing strategies and 169 values for the variables) which are listed in Supplementary table 4. For each simulation setting, we simulated 200 simulated trajectories of 100 days to obtain the bootstrap confidence interval (BCI) of the estimated infection numbers.

Results

Effectiveness of testing and physical distancing

When simulating single testing methods under the non-slum urban scenario, we found that using symptom-based diagnosis, PCR, antibody RDT or antigen RDT alone will isolate or quarantine more than 25% of the population and reduce the proportion of population infected as the isolation compliance rate increases. (Figure 3B) When isolation compliance rates are at optimistic levels (i.e. symptom-based = 20%, test-based = 90%), antigen RDT testing outperformed other methods and reduced the infection rate (computed as the proportion of population that are infected) to 47.4% [95% BCI 45.8% - 49.1%].

When simulating physical distancing alone under the baseline condition, we found that the infection number reduces as the out-of-household contact number reduces. (Figure 3C) The transmission almost stopped when non-household contact number was reduced by 80% (Re = 1.01), compared to the scenario without physical distancing (Re = 2.48) where 72.4% [95% BCI: 70.6% - 74.2%] of the population was infected. When simulating physical distancing with symptom-based diagnosis, PCR testing, antibody RDT or antigen RDT using the optimistic compliance rates for isolation and quarantine (Table 2), we found these detection and quarantine methods could mitigate the transmission. When physical distancing reduces 60% of non-household contact, using antigen RDT testing for isolation and quarantine performs the best by reducing infection rate to 14.1% (95% BCI 12.5% - 15.7%).

When simulating disease outbreak in relation to combined testing strategies (Supplementary Table 2), we found that the symptom-based diagnosis with auxiliary PCR testing (type 1 combined strategy) could provide better outcomes (48.9% infected [95% BCI: 46.4% - 50.5%]) than either method alone, while additional antibody testing (type 2 combined strategy) did not provide noticeable containment power (46.9% infected). (Figure 3D) Antigen RDT testing with auxiliary PCR (type 3 combined strategy) provided the strongest mitigating effect, with 41.0% [95% BCI: 39.4% - 42.7%] of the population infected. Though the combined effect of antigen RDT and PCR testing is not much stronger than using antigen RDT testing alone. When physical distancing reduces out-of-household contact number by 60%, the transmission is delayed and the infection rate is reduced to 21.8%. When type 3 combined strategy is performed with physical

distancing, the infection rate is reduced to 5.6%. (Figure 4A) Combined, these results show that although combination strategies could mitigate the transmission in the non-slum urban setting, delaying the transmission with physical distancing is essential for containing the outbreaks.

Transmission and containment in different community settings

When simulated outbreaks under different community settings, we found the transmission in rural areas (Food and Agriculture Organization, 2018) were slower and the final epidemic sizes were smaller (29.2% infected [95% BCI: 26.6% - 31.9%]) than the urban settings (Figure 4A, Supplementary Figure 2, Supplementary Table 2). Using antigen RDT for case finding and contact tracing could reduce the infection rate to 11.6% [95% BCI: 10.1% - 13.1%]. When simulating a moderate physical distancing by blocking 40% out-of-household contacts in rural communities, we observed a significant containment of the outbreak (6.2% infected), while adding antigen RDT for case finding and contact tracing could further reduce infection rate to 2.4%. Results from the non-slum urban setting is the baseline community discussed in the previous section. Slum setting is simulated with a large household size (mean = 15) and a high proportion (50%) of contacts between members from the same household. Infection rate is high (mean = 82.9%) and using antigen RDT with limited PCR tests could mitigate the transmission (infection rate 54.9% [95% BCI: 54.0% - 55.9%]). While physical distancing (reducing 60% of out-of-household contacts) could only mitigate the transmission in slums (infection rate = 64.0%), applying case finding and contact tracing using antigen RDT and limited PCR tests could further reduce the infection rate to 32.6%.

The distributions of infection rates show substantial uncertainty for rural areas and for non-slum urban areas when physical distancing is in place. (Figure 4A, Supplementary Table 2) To account for the uncertainty, we defined the stochastic extinction events as the trajectories that infected less than 5% of the population. Under the three settings considered, the probability of stochastic extinction increases when testing, isolation and quarantine are implemented. When physical distancing and case finding using antigen RDT are implemented under the rural setting, 80% of the simulated trajectories would lead to an stochastic extinction event, while stochastic

extinctions happened in 25% of the trajectories when no NPI is imposed. Under the non-slum urban setting, the stochastic extinction events happened in 44.5% of the trajectories when physical distancing and type 3 combined strategy are implemented, which is a much larger proportion compared to 4% when no NPI is implemented. For the slum setting, physical distancing (reducing 60% of out-of-household contacts) increases stochastic extinction rate slightly from 2% to 5%. When physical distancing is supplemented with type 3 strategy, the stochastic extinction probability increases to 13.5%.

The impact of RDT sensitivity, tracing and assumed parameters

The most effective containing strategy identified above involves antigen RDT whose sensitivity varies across studies. (Pilarowski et al., 2020; Scohy et al., 2020) When testing strategy involves antigen RDT, our simulations show that the containment effect increases as the RDT sensitivity increases. (Figure 4B) To reach a similar containment effect as in Figure 4A, which assumes an antigen RDT sensitivity of 56% (70% sampling success rate and 80% kit sensitivity), the kits deployed should have a sensitivity above 40%.

For the role of contact tracing, we found when the quarantine compliance rate increased from 30% to 100% under the type 3 strategy, the average infection rate reduced from 15.7% to 9.5% in rural settings, from 53.2% to 36.5% in non-slum urban settings, and from 66.5% to 49.5% in slum settings. (Figure 4C) Note only contacts that are of isolated infectors and successfully traced are subject to the quarantine. With no close contact quarantine measures, the combination strategies show no significant effect on reducing infection numbers (Supplementary Figure 3). Moreover, we found that the number of infected individuals discovered by testing is less than those discovered by contact tracing when the contact quarantine compliance rate is above 25%. (Supplementary Figure 4A)

The impact of other testing parameters on the containment outcomes are summarised in Supplementary table 3 using R^2 and P-values. Among these parameters, strong correlation between isolation consent rates and containing effectiveness are observed for all strategies and

settings. Days from symptom onset to isolation, quarantine consent rate of contacts and tracing success rate are correlated with containing effectiveness in two urban settings, while less impactful in the rural setting. Duration of close contact tracing is only effective for type 2 strategy under all three settings, suggesting antibody RDT requires contact tracing through a longer period to be effective. Additionally, we found that starting testing and quarantine after 10% of the population are infected could protect 31% of the healthy population under a non-slum urban setting and 21% of the healthy population under the slum setting (Supplementary Figure 4B).

Discussion

Our primary goal in this study is to identify optimal COVID-19 containment policies for LIMCs where NPIs are critical due to their limited vaccine supply and hospital capacity. (Walker et al., 2020) To capture demographic characteristics of LMICs, notably younger population, large household sizes and large rural population, we designed our agent-based model from two perspectives. Firstly, we constructed synthetic population and contact networks that incorporate age profiles, household sizes and contact structures. Secondly, we configured three community settings which have contacts of different frequencies and distributions to study the transmission and containment of COVID-19 in rural and urban populations. The transmission dynamics and NPI effectiveness varies largely across community settings which is consistent with observations that outbreaks have very different scales among LMICs. (Makoni, 2020; Nordling, 2020) Therefore, containment strategies should be designed for specific settings: mild NPI in rural regions where activities are mostly outdoor might provide a similar containment effect as strict NPI in urban areas where contacts happen outside households but indoors. Our model discovered another level of variability where similar epidemic start points could result in completely different epidemic sizes. The distribution of epidemic sizes tends to follow a bimodal pattern where new cases either infect the majority of the population or end up in stochastic extinctions. This pattern is most manifest in rural settings where contacts are more clustered within households or in urban settings with physical distancing.

Our results also suggested antigen RDT could be applied for containing the epidemic. Though the containing power subjects to the test sensitivity and community scenario, our results suggested high quality kits that have a sensitivity above 50% for the rural setting and above 40% for urban settings will provide similar containment power shown in our simulation. However, the detrimental effect of false negative test results might negate the containment effect, which requires careful evaluation of the kit sensitivity in real-world settings. (Bock et al., 2017) Therefore, we propose to supplement antigen RDT to PCR tests in the urban settings where PCR tests are available. Other case finding methods including antibody RDT and symptom-based diagnosis are effective in rural settings or physically-distanced non-slum urban settings. Both settings have relatively small numbers of out-of-household contacts, which allows case finding and quarantine to slow down the spread. Note all the case findings are based on an optimistic assumption of isolation consent rate (i.e. symptom-based = 20%, test-based = 90%), which remains to be validated in real-world settings.

The effectiveness of physical distancing varies across community settings: in the rural setting, a moderate physical distancing alone could mitigate the transmission to an infection rate of lower than 10%; in the non-slum urban setting, physical distancing is an essential supplement to testing and tracing if we want to reduce the infection rate to below 10%; in the slum setting, physical distancing is less effective. In contrast, contact tracing is an essential component of containing strategy in all community settings. More importantly, contact tracing could provide containing power even when simulating a low quarantine consent rate of contacts (30%) and a short tracing time (3 days). As many LMICs have field healthcare professionals who could perform contact tracing, (Shapiro et al., 2012) it would be a realistic and essential measure to contain the outbreaks, especially that we have shown that testing alone without contact tracing is not effective.

There are some limitations in our study. Firstly, our simulated population is an approximation to the communities in LMICs and is limited by the lack of empirical evidence from LMICs. Therefore, a majority of the parameters are set heuristically rather than by empirical evidence.

Our simulation might be improved using detailed demographic data for LMICs, such as those collected from the Office of National Statistics (ONS) in the UK. Secondly, like many simulation studies, we had to choose our parameters from empirical studies that are not consistent with each other. (Omori et al., 2020) This difficulty is most pronounced when we are setting the parameters for age-dependent susceptibility and asymptomatic rate of the infected. Lastly, we scaled up our model by replicating simulations on independent contact networks (200,000 individuals divided into 200 populations of 1,000 individuals) due to the computation constraint of fitting large network models. Compared to simulations on larger networks, (Hinch et al., 2020) our strategy could not capture preparedness triggered by cases from nearby communities or repeated introduction of cases. A simulation framework that simulates large contact networks might provide insights to better coordinate policies for large communities.

Table 2: Summary of testing and NPI parameters. Last column shows the sources for cited parameters; values of assumed parameters are used in the containment simulations shown in Figure 4, while separate sensitivity analyses are performed for each assumed parameter (Supplementary Table 3 and Supplementary Table 4). For rationales behind the chosen value for assumed parameters, see Supplementary Methods.

Figure 1: Schematic representation of methodology. A) For each parameter setting we simulated 20 synthetic populations and inferred the contact network with ERGM, using contact data over age groups and household structure. At each simulation step, a contact network is sampled from the ERGM, where we simulate the transmission of SARS-CoV-2. B) We evaluated the effect of physical distancing by reducing the sampling probability of out-of-household contacts. Detection, isolation, contact tracing and quarantine are also simulated using the contact networks.

Figure 2: Properties of simulated outbreaks from the agent-based model. A) Example outbreak in a network composed of 1000 individuals, simulated under the non-slum urban setting without NPI. The left, middle and right panel show the distributions of infected individuals (red dots) on day 20, day 30 and day 40 from the day that initial cases are imported. The network structure is fixed for visualization, while in simulation a different contact network is sampled each day. B) Comparison of the simulated contact number distribution with those computed from the cited Uganda survey data. The simulated contact number distribution is computed by sampling 100 daily contact realizations from each of the 20 synthetic populations. C) Comparison of generation time from simulation (red histogram) and that from (Ferretti et al., 2020) (blue dotted curve). D) Comparison of simulated growth curves with cited data. The red curve with shade shows the mean of daily new cases and its 95% confidence interval for 15 days, computed from 200 simulated outbreak trajectories. The blue and green dashed curves show the growth curve for the UK (by report date) and China (by onset date) before lockdown. Growth curves are scaled so that they represent the same number of total infections.

Figure 3: Evaluation of containing strategies. A) Example of case finding and quarantine in one simulated outbreak trajectory with NPIs, where a moderate physical distancing reduced 40% of the contact outside the household and the type 1 combined strategy is performed. (Supplementary Table 2) The network structure is fixed for visualization, while in simulation a

contact network is generated each day. B) Proportion of population that are infected (at the end of the trajectories) and under quarantine (max value throughout the trajectories) using symptom, PCR, antibody RDT and antigen RDT as detection methods. The dots with bars show the mean value with 95% confidence interval from 200 simulated trajectories for each isolation compliance rate. C) Proportion of population infected when physical distancing blocks different proportions of out-of-household contacts. The box shows the corresponding effective reproductive number for the level of physical distancing. The combined effect of physical distancing with each testing method shown in B is plotted with different colors. D) Trajectories showing the number of daily cases when no intervention implemented (red), when onset isolation and PCR are performed (blue), when onset isolation, PCR and antibody RDT are all performed (green) and when antigen RDT testing are used with PCR testing (purple). The curves show the mean and the shaded area shows 95% bootstrap confidence interval from 200 trajectories. Left panel shows the baseline setting (non-slum urban) and the right panel shows the same setting with physical distancing imposed (60% reduction of contact outside household, Re = 1.57).

Figure 4: Boxplots of epidemic sizes under different simulation settings. A) Boxplots of infection rates under different containing strategies and in different community settings. For each of the three community settings, 200 simulations are performed for different NPI strategies, with (green boxes) or without physical distancing (orange boxes). B) Boxplots of infection rates for each community setting when applying antigen RDT of various sensitivity. The blue boxes show the infection rate when applying the most effective testing strategy identified in the upper panel, with different antigen RDT sensitivity. C) Boxplots of infection rates for each community setting when different quarantine compliances rates of traced contacts are simulated. The blue boxes show the infection rates when simulating containment using the most effective testing strategy

identified in the first panel. Each dot represents the epidemic size of one bootstrap trajectory. The red dashed line shows an infection rate at 5%, dots below which are defined as stochastic extinction events.

Supplementary Tables and Figures

Age group (in years)	Uganda	South Africa	Kenya	Nigeria
0-14	48.10%	29.20%	41.90%	44.00%
15-24	20.30%	19.30%	19.50%	19.00%
25+	31.60%	51.50%	38.60%	37.00%
Household Size (members)				
1	11.00%	27.00%	19.00%	16.00%
2-3	22.00%	35.00%	28.00%	26.00%
4-5	27.00%	23.00%	30.00%	26.00%
6+	40.00%	15.00%	23.00%	32.00%

Supplementary Table 1: Summary of the demographic information used in the study. The age and household sizes distribution are cited from the United Nation. (Department of Economic and Social Affairs, 2020; United Nation, 2017)

NPIs	Strategy detail			Infection rate		
	Rural	Non-slum urban	Slum	Rural	Non-slum urban	Slum
No intervention	NA			29.2% (0.4% - 46.7%)	70.2% (70.5% - 77.4%)	82.9% (82.1% - 86.6%)
Type 1 combined strategy	Onset isolation + close contact quarantine	Onset isolation + PCR + close contact quarantine	Onset isolation + limited PCR + close contact quarantine	19.1% (0.4% - 36.3%)	48.9% (46.4% - 55.0%)	62.4% (57.2% - 67.8%)
Type 2 combined strategy	Onset isolation + antibody RDT + close contact quarantine	Onset isolation + PCR + antibody RDT + close contact quarantine	Onset isolation + limited PCR + antibody RDT + close contact quarantine	16.5% (0.5% - 0.5%)	46.9% (44.2% - 44.2%)	58.9% (53.5% - 53.5%)
Type 3 combined strategy	Antigen RDT + close contact quarantine	Antigen RDT + PCR + close contact quarantine	Antigen RDT + limited PCR + close contact quarantine	11.6% (0.3% - 26.4%)	41.0% (38.2% - 48.5%)	54.9% (49.9% - 61.1%)
Social distancing	Reducing 40% of non-household contact	Reducing 60% of non-household contact	Reducing 60% of non-household contact	6.2% (0.3% - 19.1%)	21.8% (0.3% - 41.8%)	64.0% (61.5% - 71.9%)
Type 1 combined strategy + social distancing	Strategy 1 + reducing 40% of non-household contact	Strategy 1 + reducing 60% of non-household contact	Strategy 1 + reducing 60% of non-household contact	4.0% (0.3% - 11.8%)	8.7% (0.4% - 22.1%)	38.3% (0.6% - 49.8%)
Type 2 combined strategy + social distancing	Strategy 2 + reducing 40% of non-household contact	Strategy 2 + reducing 60% of non-household contact	Strategy 2 + reducing 60% of non-household contact	3.6% (0.3% - 10.8%)	7.4% (0.3% - 20.5%)	38.6% (32.8% - 46.7%)
Type 3 combined strategy + social distancing	Strategy 3 + reducing 40% of non-household contact	Strategy 3 + reducing 60% of non-household contact	Strategy 3 + reducing 60% of non-household contact	2.4% (0.3% - 6.7%)	5.6% (0.3% - 15.8%)	32.6% (0.9% - 44.0%)

Supplementary Table 2: Summary of NPI strategies for different settings and the mean of infection rate. The mean of infection rate is computed from 200 simulated trajectories of 100 days for each strategy. The range in the bracket shows the 10% and 90% quantiles of the infection rates from 200 bootstrap samples.

Supplementary Table 3: The impact of NPI parameter setting on the effectiveness of containment. Panel A-C shows sensitivity analysis under rural, non-slum urban and slum settings. The coefficient of determination (R^2) shows the proportion of variance in the final infected number (under each containing strategy) that is captured by the testing parameters; The P-values in the bracket show the rate of type one error of rejecting the null hypothesis that the parameter is not correlated with outcome.

ID	Description	Values								
1	Basic reproduction number	1.5	2	2.5	3	3.5				
2	Number of daily contact	2	4	7	10	14				
3	Number of intial inporting cases	1	2	5	8	15				
4	Healthcare seeking rate	30%	50%	70%	90%	100%				
5	Asymptomatic rate	10%	20%	30%	40%	50%	60%	70%	80%	90%
6	Transmission ratio for isolated patients	5%	10%	15%	20%	25%				
7	Daily PCR tests per 1000 population for slum	Not available	1	2	10	20	50	1000		
8	Community size	100	1000	2000						
9	Infection number in 1000 to trigger containment	No delay	5	20	50	100	250	500		
10	Percentage of contacts that are with a member of household, fixing the number of total contacts	20%	40%	60% (did not converge for slum settings)	80% (did not converge for three settings)					
11	Social distancing, which is computed as the proportion of non-household contact that is stopped.	0%	20%	40%	60% (did not converged for rural setting)	80% (did not converged for rural and slum settings)				
12	Non-household contact trace successful rate	0%	15%	35%	55%	75%	85%	95%		
13	Delay after tested postive to isolation (days)	0	1	3	5					
14	Duration of contact tracing, counted from the day of isolation (days)	Symptom screening/Antigen RDT = 1; Antibody RDT = 6; PCR = 3	Symptom screening/Antigen RDT = 3; Antibody RDT = 8; PCR = 5	Symptom screening/Antigen RDT = 5; Antibody RDT = 10; PCR = 7	Symptom screening/Antigen RDT = 7; Antibody RDT = 12; PCR = 9					
15	Delay after onset for PCR testing results (days); contact tracing duration is set to be same as the delay, as we assume healthcare workers will start contact tracing once they identify an individual with onset.	0	1	3	5	7	10	14		
16	Delay after onset for antibody sampling (days); contact tracing duration is set to be same as the delay, as we assume healthcare workers will start contact tracing once they identify an individual with onset.	5	6	7	8	9	10	11		
17	Seroconversion rate	opimistic: half of individual has detectable antibody 7 days after onset	opimistic: half of individual has detectable antibody 12 days after infection	conservative: half of individual has detectable antibody 9 days after onset						
18	Test acceptance rate (conditional on an individual seek healthcare)	Antibody (blood sample) = 30%; PCR/Antigen (swab sample) = 40%	Antibody (blood sample) = 50%; PCR/Antigen (swab sample) = 60%	Antibody (blood sample) = 70%; PCR/Antigen (swab sample) = 80%	90%					
19	Sympotom-based isolation consent rate, simulated with other testing measures	10%	20%	30%	40%	50%	60%	70%	80%	90%
20	Sympotom-based isolation consent rate (simulation with only symptome detection, no other detecting measures)	10%	20%	30%	40%	50%	60%	70%	80%	90%
21	PCR isolation consent rate (simulation with only PCR testing, no other detecting measure)	10%	20%	30%	40%	50%	60%	70%	80%	90%
22	Antibody RDT isolation consent rate (simulation with only antibody RDT, no other detecting measure)	10%	20%	30%	40%	50%	60%	70%	80%	90%
23	Antigen RDT isolation consent rate (simulation with only antigen RDT, no other detecting measure)	10%	20%	30%	40%	50%	60%	70%	80%	90%
24	close contact quarantine compliance rate (conditional on the infector consent to be isolated)	Symptom screen = 10%; Testing = 30%	Symptom screen = 30%; Testing = 50%	Symptom screen = 50%; Testing = 70%	Symptom screen = 70%; Testing = 90%	Symptom screen = 90%; Testing = 100%				

Supplementary Table 4: Parameter settings for sensitivity analysis. The Description explains what variables are changed and rows contain the values of each variable used for simulation. For each value we performed the simulation for baseline and three types of containing strategies under the rural, non-slum urban and slum settings.

ID	Description	Values				
2	**Number of daily contact**	**2**	**4**	**7**	**10**	**14**
	Rural	0.99	1.00	1.00	1.00	0.14
	Non-slum urban	1.00	1.00	0.99	1.00	1.00
	Slum	1.00	0.94	0.99	1.00	1.00
9	**Community size**	**100 (did not converge for rural setting)**	**1000**	**2000**		
	Rural	0.000002 *	1.00	1.00		
	Non-slum urban	1.00	1.00	1.00		
	Slum	1.00	1.00	1.00		
11	**Percentage of contacts that are with a member of household, fixing the number of total contacts**	**20%**	**40%**	**60% (did not converge for rural setting)**	**80% (did not converge for three settings)**	
	Rural	1.00	1.00	1.00	0 *

	Slum	1.00	1.00	1.00	1.00	1.00

Supplementary Table 5: Lack-of-fit test for the ERGM inference. We performed lack-of-fit tests of the target statistics for the four variables that alter the ERGMs. IDs correspond to Supplementary Table 3. For each value (bold), we compute the P-value by comparing the 20 fitted networks with the input to the ERGMs. * shows the cases when the networks are rejected as good fits.

Supplementary Figure 1: A) Comparison of simulation using age distribution and household sizes for Kenya, Nigeria, South Africa and Uganda. B) Comparison of fitted age-mixing contact matrix with those cited from survey data. The color scale shows the total number of contacts for each mixing within the populations. C) Serological conversion rate cited for this study. (Wölfel et al., 2020) Blue vertical line shows the assumed time point when samples were collected after individuals were infected.

Supplementary Figure 2: Summary of averaged outbreak trajectories in rural, non-slum urban and slum settings. A-B) Averaged trajectories of outbreaks under rural setting and those with three NPI containing strategies. Left panel shows the simulation without physical distancing and the right panel shows simulation with a physical distancing that blocks 40% of non-household

contacts. C-D) Same averaged trajectories under non-slum urban setting; Left panel shows simulation without physical distancing and right panel shows simulation with a physical distancing that blocks 60% of non-household contacts. E-F) Same averaged trajectories under slum setting; Left panel shows simulation without physical distancing and right panel shows simulation with a physical distancing that blocks 60% of non-household contacts. The curves are the mean value of daily infected numbers for a synthetic population of 1000; The shaded area indicated the 95% confidence interval of the estimation; Both mean and confidence intervals are computed from 200 simulated outbreaks.

Supplementary Figure 3: Averaged trajectories when no close contact tracing is performed under rural, non-slum urban and slum settings. he curves are the mean value of daily infected numbers for a synthetic population of 1000; The shaded area indicated the 95% confidence interval of the estimation; Both mean and confidence interval are computed from 200 simulated outbreaks.

Supplementary Figure 4: Evaluation of close contact tracing and delayed responses. A) Proportion of total cases isolated (red dots) or quarantined (green dots) varies as the compliance

rate of quarantine a close contact of a confirmed case changes. B) Implementation of containing measures after a certain proportion of the population was infected could still protect a proportion of the population, compared to the circumstances with no intervention. All simulations are performed for rural, non-slum urban and slum settings.
