ABSTRACT

Continuous risk of recurrence scores (CRS) based on tumor gene expression are vital prognostic tools for breast cancer (BC). Studies have shown that Black women (BW) have higher CRS than White women (WW). Although systemic injustices contribute substantially to BC disparities, evidence for biological and germline contributions is emerging. We investigated germline genetic associations with CRS and CRS disparity through a Transcriptome-Wide Association Study (TWAS). In the Carolina Breast Cancer Study, using race-specific predictive models of tumor expression from germline genetics, we performed race-stratified (N=1,043 WW, 1083 BW) linear regressions of three CRS (ROR-S: PAM50 subtype score; Proliferation Score; ROR-P: ROR-S plus Proliferation Score) on imputed Genetically-Regulated tumor eXpression (GReX). Using Bayesian multivariate regression and adaptive shrinkage, we tested TWAS-significant genes for associations with PAM50 tumor expression and subtype to elucidate patterns of germline regulation underlying TWAS-gene and CRS associations. At FDR-adjusted $P < 0.10$, we detected 7 TWAS-genes among WW and 1 TWAS-gene among BW. Among WW, CRS showed positive associations with *MCM10, FAM64A, CCNB2*, and *MMP1* GReX and negative associations with *VAV3, PCSK6*, and *GNG11* GReX. Among BW, higher *MMP1* GReX predicted lower Proliferation score and ROR-P. TWAS-gene and PAM50 tumor expression associations highlighted potential mechanisms for TWAS-gene to CRS associations. Among BC patients, we find differential germline associations with three CRS by race, underscoring the need for larger, more diverse datasets in molecular studies of BC. Our findings also suggest possible germline *trans*-regulation of PAM50 tumor expression, with potential implications for interpreting CRS in clinical settings.

SIGNIFICANCE

We find race-specific genetic associations with breast cancer risk-of-recurrence scores (CRS). Follow-up analyses suggest mediation of these associations by PAM50 molecular subtype and gene expression, with implications for clinical interpretation of CRS.

INTRODUCTION (Manuscript Word Count = 3978/5000)

Tumor expression-based molecular profiling has improved clinical classification of breast cancer (1-3). One tool is the PAM50 assay, which integrates tumor expression of 50 genes (derived from a set of 1,900 subtype-specific genes identified in microarray studies) to determine PAM50 intrinsic molecular subtypes: Luminal A (LumA), Luminal B (LumB), Human epidermal growth factor 2-enriched (HER2-enriched), Basal-like, and Normal-like (1,4). Intrinsic molecular subtypes are strong prognostic factors for breast cancer outcomes, including recurrence and mortality. For instance, Basal-like breast cancer has substantially higher recurrence and mortality risk compared to LumA breast cancer (5-8). In recent years, continuous risk of recurrence scores (CRS) have gained traction as a potential clinical tool that encapsulates prognostic differences of breast cancer intrinsic molecular subtypes into a singular measure that can be used to guide treatment decisions. CRS include ROR-S, Proliferation score, ROR-P, and ROR-PT (1,9). ROR-P, for instance, is determined by combining ROR-S (PAM50 tumor expression-based subtype score) and Proliferation score (tumor expression of 11 PAM50 genes). ROR-PT further integrates ROR-P with information on tumor size. Studies show that CRS offer significant prognostic information beyond clinical variables (e.g., nodal status, tumor grade, age, hormonal therapy), improve adjuvant treatment decisions, and offer robust risk stratification for distant (5-10 years post diagnosis) recurrence (10-12).

In the Carolina Breast Cancer Study (CBCS), Black women (BW) with breast cancer have disproportionately higher CRS than White Women (9), and similar disparities have been noted in Oncotype Dx recurrence score (9,13). Systemic injustices, like disparities in healthcare access, explain a substantial proportion of breast cancer outcome disparities (14-17). Recent studies additionally suggest that germline genetic variation is associated with breast cancer outcomes, and these associations vary across ancestry groups (18-21). In The Cancer Genome Atlas (TCGA), BW had substantially higher polygenic risk scores for the more aggressive ER-negative subtype than WW, suggesting differential genetic contributions for susceptibility for breast cancer, especially ER-negative breast cancer (21-23). In a transcriptome-wide association study (TWAS) of breast cancer mortality, germline-regulated gene expression of four genes was associated with mortality among BW and gene expression for no genes

was associated among WW (18). However, the role of germline genetic variation in recurrence, CRS, and CRS disparity remains a critical knowledge gap. Studying genetic associations with breast cancer outcomes in BW is necessary to ensure advancements in breast cancer genetics are not limited to or generalizable in only White populations, thus aiding in decreasing health disparities.

As racially-diverse genetic datasets typically have small samples of BW, gene-level association tests can be used to increase study power. These approaches include TWAS, which integrates relationships between single nucleotide polymorphisms (SNP) and gene expression with genome-wide association studies (GWAS) to prioritize gene-trait associations (24,25). TWAS aids in interpreting genetic associations by mapping significant GWAS associations to tissue-specific expression of individual genes. Furthermore, TWAS can also prioritize novel tissue-specific gene-trait associations by using germline genetics as a causal anchor, as, under assumptions of independent assortment of alleles, or barring that, effective control for population stratification, germline genetics cannot be affected by gene expression or confounding exposures. In cancer applications, TWAS has identified susceptibility genes at loci previously undetected through GWAS, highlighting its improved power and interpretability (26-28). Previous studies show that stratification of the entire TWAS (model training, imputation, and association testing) is preferable in diverse populations, as models may perform poorly across ancestry groups and methods for TWAS in admixed populations are unavailable (18,29).

Here, using data from the CBCS, which includes a large sample of Black breast cancer patients with tumor gene expression data, we study race-specific germline genetic associations for CRS using TWAS. CRS included in this study are ROR-S, Proliferation score, and ROR-P. Using race-specific predictive models for tumor expression from germline genetics, we identify sets of TWAS-prioritized genes (TWAS-genes) associated with these CRS across BW and WW. We additionally investigate TWAS-genes for ROR-P for associations with PAM50 subtype and subtype-specific tumor gene expression to elucidate germline contributions to PAM50 subtype, and how these mediate TWAS-gene and CRS associations. Unlike previous studies that correlated tumor gene expression (as opposed to germline-regulated tumor

gene expression) with subtype or subtype-specific tumor gene expression, TWAS enables directional interpretation of observed associations by ruling out reverse causality (24,25).

MATERIALS AND METHODS

Data collection

Study population

The CBCS is a population-based study of North Carolina (NC) breast cancer patients, enrolled in three phases; study details have been previously described (30,31). Patients aged 20 to 74 were identified using rapid case ascertainment with the NC Central Cancer Registry with randomized recruitment to oversample self-identified Black and young women (ages 20-49) (9,31). Demographic and clinical data (age, menopausal status, body mass index, hormone receptor status, tumor stage, study phase, recurrence) were obtained through questionnaires and medical records. Time-to-event recurrence data were only available for CBCS Phase 3. The study was approved by the Office of Human Research Ethics at the University of North Carolina at Chapel Hill, and informed consent was obtained from each participant.

CBCS genotype data

Genotypes were assayed on the OncoArray Consortium's custom SNP array (Illumina Infinium OncoArray) (32) and imputed using the 1000 Genomes Project (v3) as a reference panel for two-step phasing and imputation using SHAPEIT2 and IMPUTEv2 (33-36). The DCEG Cancer Genomics Research Laboratory conducted genotype calling, quality control, and imputation (32). We excluded variants with less than 1% minor allele frequency and deviations from Hardy-Weinberg equilibrium at $P < 10^{-8}$ (37,38). We intersected genotyping panels for BW and WW samples, resulting in 5,989,134 autosomal variants and 334,391 variants on the X chromosome (39). We only consider the autosomal variants in this study.

CBCS gene expression data

Paraffin-embedded tumor blocks were assayed for gene expression of 406 breast cancer-related and 11 housekeeping genes using NanoString nCounter at the Translational Genomics Laboratory at UNC-Chapel Hill (4,9). These 406 breast cancer-related genes include genes part of the PAM50, P53, E2, IGF, and EGFR signatures, among others (**Supplementary Table S1**). As described previously, we eliminated samples with insufficient data quality using NanoStringQCPro (18,40), scaled distributional difference between lanes with upper-quartile normalization (41), and removed two dimensions of unwanted technical and biological variation, estimated from housekeeping genes using RUVSeq (41,42). The current analysis included 1,199 samples with both genotype and gene expression data (628 BW, 571 WW).

Statistical analysis

Overview of TWAS

TWAS integrates expression data with GWAS to prioritize gene-trait associations through a two-step analysis (**Figure 1A-B**). First, using genetic and transcriptomic data, we trained predictive models of tumor gene expression using all SNPs within 0.5 Megabase of the gene (18,25). Second, we used these models to impute the Genetically-Regulated tumor eXpression (GReX) of a gene into an external GWAS panel by multiplying the SNP-gene weights from the predictive model with the dosages of each SNP in the GWAS panel. The GReX represents the portion of tumor expression explained by *cis*-genetic regulation. We test for gene-trait associations with an outcome by running a linear regression using GReX as the primary predictor of interest. By focusing on genetically regulated expression, TWAS generally avoids instances of expression-trait association that are not consequences of genetic variation but are driven by the effect of traits on expression. If sufficiently heritable genes are assayed in the correct tissue, TWAS increases power to detect gene-trait associations and aids interpretability of results, as associations are mapped from germline genetics to individual genes (25,43).

CRS TWAS in CBCS

We adopted techniques from FUSION to train predictive models of tumor expression from *cis*-germline genotypes, as discussed previously (18,25). Motivated by strong associations between germline genetics and tumor expression in CBCS (18), for genes with non-zero *cis*-heritability at nominal $P < 0.10$, we

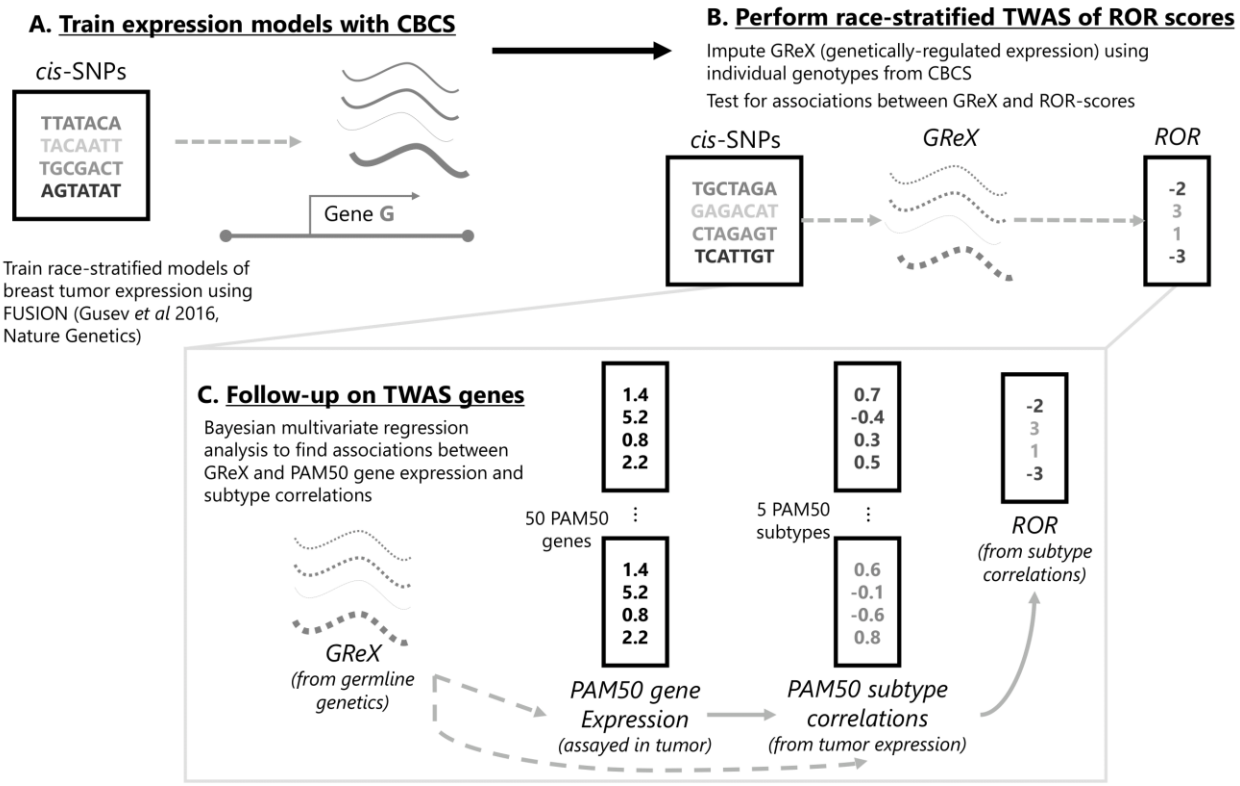

Figure 1. *Schematic of study analytic approach.* A) In CBCS, constructed race-stratified predictive models of tumor gene expression from *cis*-SNPs. B) In CBCS, imputed GReX at individual-level using genotypes and tested for associations between GReX and CRS in race-stratified linear models; only GReX of genes with significant *cis*-h^2 and high cross validation performance (R^2 > 0.01 between observed and predicted expression) considered for race-stratified association analyses. C) Follow-up analyses on TWAS-genes (i.e., genes whose GReX were significantly associated with CRS at FDR <0.10). In race-stratified models, PAM50 SCCs and PAM50 tumor expressions were regressed against TWAS-genes under a Bayesian multivariate regression and multivariate adaptive shrinkage approach.

trained predictive models for covariate-residualized tumor expression with all *cis*-SNPs within 0.5 Megabase using linear mixed modeling or elastic net regression (**Supplementary Methods, Supplementary Materials**) (44,45). We selected models with five-fold cross-validation adjusted $R^2 > 0.01$ between predicted and observed expression values, resulting in 59 and 45 models for WW and BW, respectively (**Supplementary Data**). These models also showed sufficiently strong predictive performance in external validation using TCGA data (18).

Using only germline genetics as an input, we imputed GReX in 1,043 WW and 1,083 BW, respectively, in CBCS. For samples that were not present in the training dataset, we multiplied the SNP-weights from the predictive models with the SNP dosages to construct GReX. For samples in both the training and

imputation datasets, GReX was imputed via cross-validation to minimize data leakage. We tested GReX for associations with ROR-S, Proliferation Score, and ROR-P using multiple linear regression adjusted for age, estrogen receptor (ER) status, tumor stage, and study phase (1). We corrected for test-statistic bias and inflation using a Bayesian bias and inflation adjustment method *bacon*, as TWAS are prone to bias and inflation of test statistics (46). We then adjusted for multiple testing using the Benjamini-Hochberg procedure (46,47). To compare germline effects with total (germline and post-transcriptional) effects on ROR, we assessed relationships between total tumor expression of TWAS genes and CRS using similar linear models. We were underpowered to study time-to-recurrence due to small sample size, as recurrence data was collected only in CBCS Phase 3 (635 WW, 742 BW with GReX and recurrence data; 183 WW, 283 BW with tumor expression and recurrence data). For significant TWAS-identified genes for CRS (FDR-adjusted $P < 0.10$), we conducted a follow-up permutation test: we shuffle the SNP-gene weights in the predictive model 5,000 times to generate a null distribution and compare the original GReX-CRS associations to this null distribution. This permutation test assessed whether the TWAS association provides more tissue-specific expression context, beyond any strong SNP-CRS associations at the genetic locus (25).

PAM50 assay and ROR-S, Proliferation score, and ROR-P calculation

As described previously (1), using partition-around-medoid clustering, we calculated the correlation with each subtype's centroid for study individuals based on PAM50 expressions (10 PAM50 genes per subtype). The largest subtype-centroid correlation defined the individual's molecular subtype. ROR-S was determined via a linear combination of the PAM50 subtype-centroid correlations (SCCs); the coefficients to the PAM50 SCCs in the linear combination are positive for Luminal B, HER2-enriched, and Basal-like and negative for Luminal A (1). Proliferation score was computed using log-scale expression of 11 PAM50 genes, while ROR-P was computed by combining ROR-S and Proliferation score.

Assignment of PAM50 gene to subtype was based on PAM50 gene centroid values for each subtype; the subtype assigned to a PAM50 gene corresponded to the largest positive centroid value across subtypes for that gene. Subtype assignment through this "greedy algorithm" are specific to this study and represent

a simplified reality (e.g., ESR1 classified as part of Luminal A subtype only even though ESR1 expression correlates with both Luminal A and to a slightly lesser degree Luminal B subtype). Moreover, subtype assignment for this portion of analyses was conducted only for visual comparison of patterns of associations between TWAS-genes and PAM50 tumor gene expressions (i.e., subtype assignment in this portion of analyses had no bearing on continuous ROR score calculations or subtype-centroid correlations).

Bayesian multivariate regressions and multivariate adaptive shrinkage

As previously noted (1), CRS are functions of PAM50 SCCs and gene expression profiles. Thus, we followed up on CRS-associated TWAS-genes by studying their associations with PAM50 SCCs and gene expression. We assessed TWAS-genes (for ROR-P) in relation to SCCs and PAM50 tumor gene expression (**Figure 1C**). Importantly, consistent with the original formulation of ROR-S, we did not consider normal-like subtype and normal-like subtype specific genes; subtype-specific genes were determined using a greedy assignment algorithm where the highest centroid value across subtypes for a given PAM50 gene determined that PAM50 gene's subtype. This classification scheme offers analytic simplicity but is an oversimplification for some PAM50 genes such as ESR1, which shows high centroid values for both LumA and LumB, albeit highest for LumA (ESR1 was assigned as a LumA gene in this study). We found that none of our TWAS-genes were within 1 Megabase of PAM50 genes and that most TWAS-genes were not on the same chromosome as PAM50 genes (**Supplementary Table S2**). Existing gene-based mapping techniques for *trans*-expression quantitative trait loci (eQTL) (SNP and gene are separated by more than 1 Megabase) mapping include *trans*-PrediXcan and GBAT (48,49). We employed Bayesian multivariate linear regression (BtQTL) to account for correlation in multivariate outcomes (SCCs and PAM50 gene expression) in association testing. BtQTL improves power to detect significant *trans*-associations, especially when considering multiple genes with highly correlated (>0.5) expression (**Supplementary Methods**, **Supplementary Figures S1-S2, Supplementary Materials**). Lastly, we conducted adaptive shrinkage on BtQTL estimates using mashr, an empirical Bayes method to estimate patterns of similarity and improve accuracy in associations tests across multiple outcomes (50). mashr

outputs revised posterior means, standard deviations, and corresponding measures of significance (local false sign rates, or LFSR).

RESULTS

Race-specific associations between GReX and CRS

We performed race-specific TWAS for CRS to investigate the role of germline genetic variation in CRS and CRS racial disparity. We identified 8 genes (*MCM10, FAM64A, CCNB2, MMP1, VAV3, PCSK6, NDC80, MLPH),* 8 genes (*MCM10, FAM64A, CCNB2, MMP1, VAV3, NDC80, MLPH, EXO1)*, and 10 genes (*MCM10, FAM64A, CCNB2, MMP1, VAV3, PCSK6, GNG11, NDC80, MLPH, EXO1)* whose GReX was associated with ROR-S, proliferation, and ROR-P, respectively, in WW, and 1 gene (*MMP1*) whose GReX was associated with proliferation and ROR-P in BW at FDR-adjusted $P < 0.10$ (**Figure 2A, 2B**). No associations were detected between GReX and ROR-S among BW. We refer to genes with statistically significant TWAS associations (FDR-adjusted $P < 0.10$) as TWAS-genes. Among these identified genes, only genes that are not part of the PAM50 panel (i.e., excluding *NDC80, MLPH, EXO1*) were considered in downstream permutation and TWAS-gene follow up analyses (**Figure 1C**), as we wished to focus investigation on relationship between non-PAM50 TWAS-genes and PAM50 (tumor) genes.

Among WW, increased GReX of *MCM10*, *FAM64A*, *CCNB2*, and *MMP1* were associated with higher CRS while increased GReX of *VAV3*, *PCSK6*, and *GNG11* were associated with lower CRS (**Figure 2A**). Among BW, increased GReX of *MMP1* was associated with lower CRS (Proliferation, ROR-P, but not ROR-S) (**Figure 2A**). Briefly, to contextualize the functions of these TWAS-identified genes, *MCM10* is involved in DNA replication, *FAM64A* and *CCNB2* are implicated in progression and regulation of the cell cycle, and *MMP1*, like the broader *MMP* family, is involved in the breakdown of the extracellular matrix (51-55). *GNG11* and *VAV3* are involved in signal transduction: *GNG11* as a component of a transmembrane G-protein and *VAV3* as a guanine nucleotide exchange factor for GTPases (56,57).

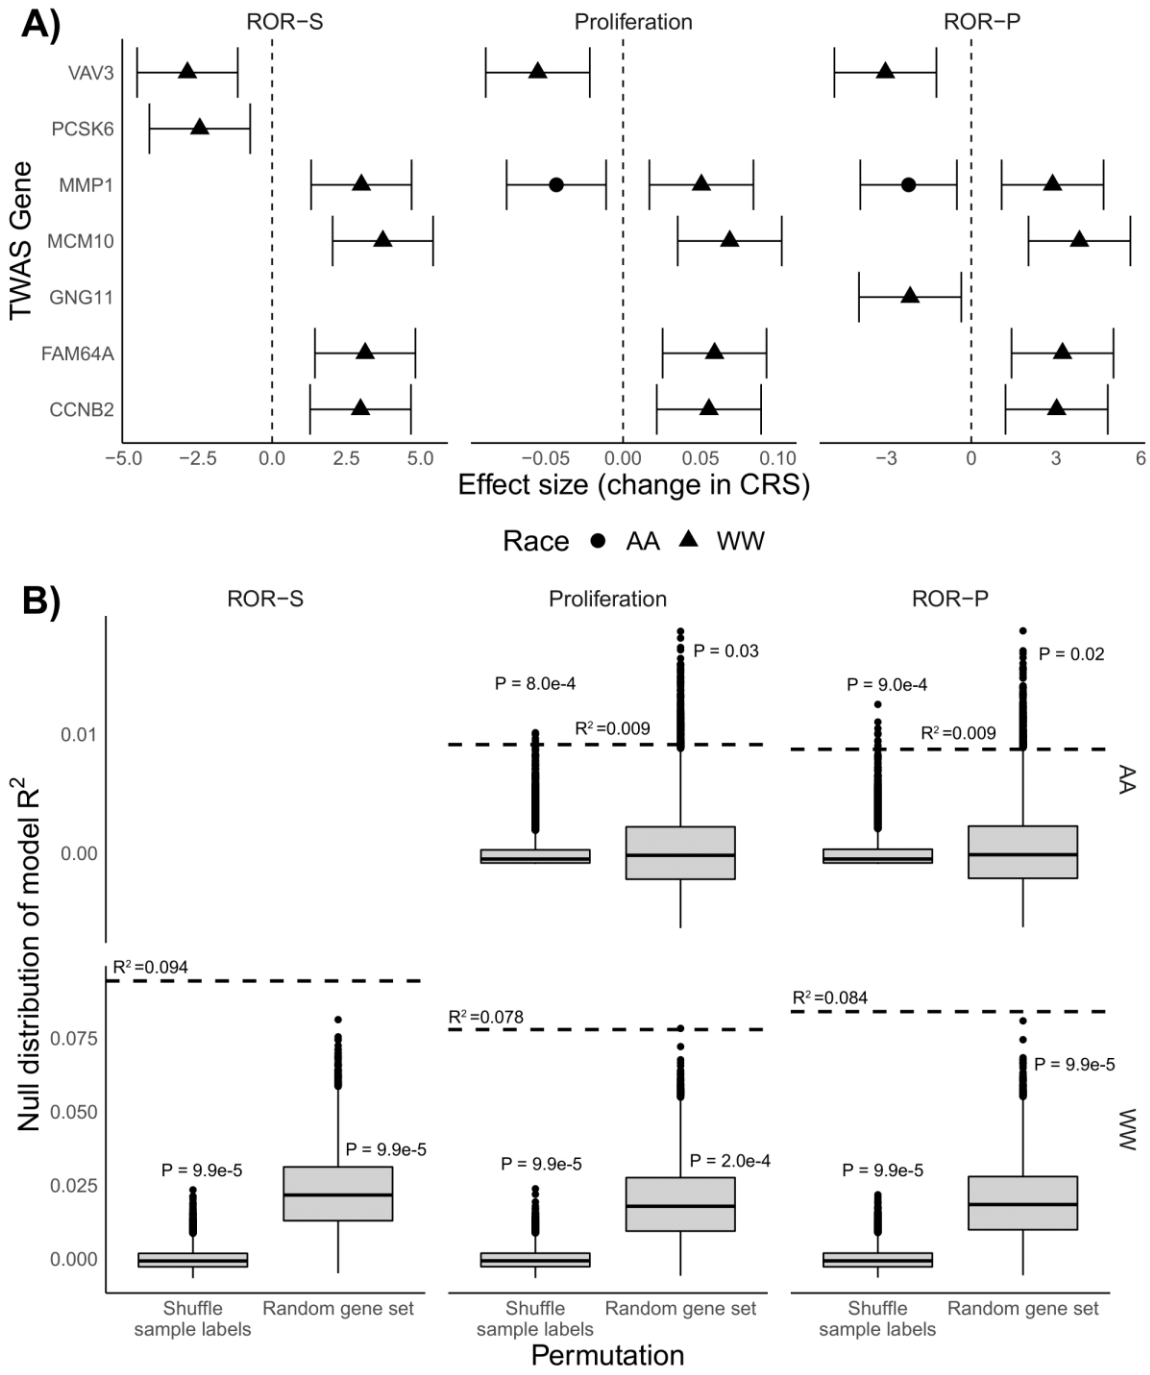

Figure 2. *Permutation tests and associations between TWAS-genes and CRS for WW and BW.* A) Effect estimates correspond to change in ROR-S, Proliferation score, and ROR-P per one standard deviation increase in TWAS-gene expression (i.e., one standard deviation increase in GReX of gene). Triangle denotes WW and circle denotes BW. B) Boxplots correspond to null distributions (shuffled GReX-sample labels on left, random set of genes on right) of covariates residualized-R^2 for regressions of CRS on TWAS-genes. Null distributions are provided for 10,000 permutations of the GReX-sample labels and 10,000 random sets of genes. Dashed horizontal lines correspond to observed covariates residualized-R^2.

Associations between tumor expression of TWAS-genes and CRS were concordant, in terms of direction of association to germline-only effects among WW; findings were discordant among BW where higher

tumor expression of MMP1 was associated with higher CRS (**Table 1, Supplementary Table S3).**

Permutation testing provides context to TWAS-gene and CRS associations

To assess the statistical significance for the observed variance in CRS explained by significant TWAS-genes, we conducted two permutation analyses. First, we assessed the per-gene significance of the GReX-CRS associations, conditional on the SNP-trait effects at the locus, by generating a null distribution for the GReX-CRS association via shuffling the SNP-gene weights from the predictive models 5,000 times. We generated a permutation P-value for the GReX-CRS association by comparing to this null distribution. Here, we found that all GReX-CRS associations showed significance in permutation testing at FDR-adjusted $P < 0.05$ (**Table 1**). These per-TWAS-gene permutation tests show that GReX (of TWAS-genes) adds more context beyond the genetic architecture at the locus and provide evidence that germline genetics to TWAS-gene expression relationship mediates, to some level, the complex genetic effects on CRS.

Next, we quantified the percent variance explained of CRS by the TWAS genes, in aggregate, by calculating the model adjusted-R^2 for a regression of covariate-residualized CRS on GReX all TWAS-genes. To context these model adjusted-R^2, we conducted two permutation tests. First, we permuted the sample labels for covariate-residualized CRS 10,000 times and computed the model adjusted R^2 at each iteration to generate a null distribution for adjusted R^2 between TWAS-genes and CRS. Across WW and BW, the observed R^2 of TWAS-genes against CRS (7-10% among WW and 1% among BW) were statistically significant against the respective null distributions (P-values and distributions in **Figure 2B**). Permutation tests for analyses of tumor expression of TWAS-genes and CRS are available in **Supplementary Figure S3**. Second, we wanted to assess if the GReX of these sets of TWAS-genes (7 in WW and 1 in AA) explained more of the variance in CRS than the GReX of a randomly selected set of genes of the same size. Previous studies have shown that the tumor expression of a set randomly selected genes is likely to be predictive of breast cancer outcomes; we wished to investigate this phenomenon on the GReX level (58,59). Over 10,000 repetitions, we randomly selected 7 and 1 genes in WW and AA subjects, respectively, ran a multivariable regression, and calculated the model adjusted-R^2

to generate another null distribution. Here again, we found that the true model R^2 outperformed the null distribution, all showing permutation $P < 0.05$ in these settings (**Figure 2B**). These permutation tests show that our TWAS-prioritized genes, taken together, appreciably explain differences in CRS.

Associations between TWAS-genes and PAM50 subtype correlations and gene expression

As CRS are constructed from PAM50 subtype-specific correlations and gene expression profiles, we further studied associations between GReX of TWAS-genes and PAM50 SCCs and gene expression to understand how PAM50 subtype and gene expression mediate TWAS-gene and CRS associations. Among WW, a one standard deviation increase in *FAM64A* and *CCNB2* GReX resulted in significantly increased Basal-like SCC while an identical increase in *VAV3*, *PCSK6*, and *GNG11* GReX resulted in significantly increased Luminal A SCC. The magnitude of increase in correlation for respective subtypes per TWAS-gene was approximately 0.05, and most estimates had credible intervals that did not intersect the null**.** Among WW, associations between HER2-like SCC and TWAS-genes followed similar patterns to associations for the Basal-like subtype, although associations for HER2 were more precise (**Figure 3A**). We found predominantly null associations between TWAS-genes and Luminal B SCC among WW (**Figure 3A**). Unlike in WW, for BW, an increase in *MMP1* GReX was not associated with Luminal A, HER2 or Basal-like SCCs. Instead, among BW, *MMP1* GReX was significantly negatively associated with Luminal B SCC. Estimates from univariate regressions are provided in **Supplementary Tables S4-S7.**

For both WW and BW, the pattern of associations between TWAS-genes and PAM50 tumor expression were predominantly congruent with observed associations between TWAS-genes and PAM50 SCCs as well as TWAS-genes and CRS (**Figure 4, Supplementary Tables S8-S11**). In WW, a one standard deviation increase in *CCNB2* GReX was associated with significantly increased *ORC6L*, *PTTG1*, and *KIF2C* (Basal-like genes) expression and *UBE2T* and *MYBL2* (LumB genes) expression. By contrast, a one standard deviation increase in *PCSK6* GReX significantly increased *BAG1*, *FOXA1*, *MAPT,* and *NAT1* (LumA genes) expression (**Figure 3B**). While increased *MMP1* GReX was associated with significantly increased expression of *ORC6L* (basal-like gene), *MYBL2,* and *BIRC5* (LumB genes) among WW, this was not the case among BW. Instead, increased *MMP1* GReX among BW was significantly

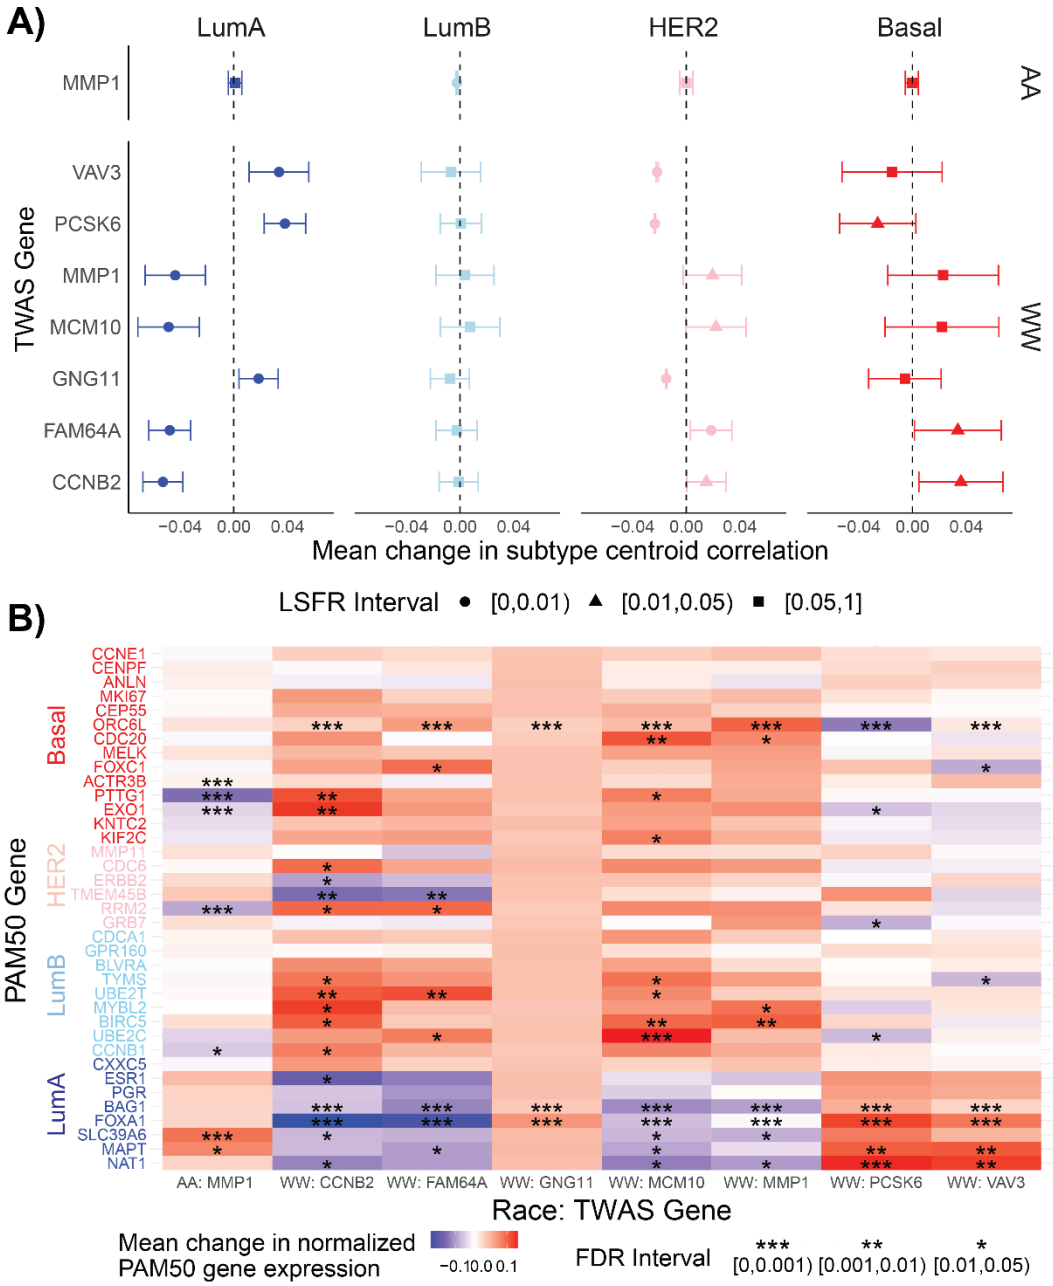

Figure 3. *Associations between TWAS-genes and PAM50 SCCs and gene expression.* A) Among AA (top) and WW (bottom), associations between TWAS-genes and PAM50 SCCs using Bayesian multivariate regression and multivariate adaptive shrinkage. Effect estimates show change in SCCs (range -1 to 1) for one standard deviation increase in TWAS-gene GReX. Circle, triangle, and square denote corresponding LFSR intervals for effect sizes. B) Heatmap of change in $\log_2$ normalized PAM50 tumor expression for one standard deviation increase in TWAS-GReX. *, **, *** denote FDR intervals for effect sizes.

associated with increased expression of *SLC39A6* (LumA gene) and decreased expression of *ACTR3B, PTTG1*, and *EXO1* (Basal-like genes) (**Figure 3B**). Associations between TWAS-genes and PAM50 genes provide a granular, gene interaction level view into the mediation of the TWAS-gene and CRS

association, suggesting that *trans*-regulation of subtype-specific PAM50 genes by TWAS-genes in breast tumors could be a possible contributor to subtype formation/maintenance and, subsequently, CRS and recurrence.

DISCUSSION

Through TWAS, we identified 7 and 1 genes among WW and BW, respectively, for which genetically-regulated breast tumor expression was associated with CRS and underlying PAM50 gene expression and subtype. Among WW, these 7 TWAS-genes explained between 7-10% of the variation in CRS, a large and statistically significant proportion of variance. Among BW, the singular TWAS-gene explained a statistically significant ~1% of the variation in Proliferation score and ROR-P. There are two key novel aspects to this study. First, existing literature on associations between tumor gene expression and recurrence (for which CRS are a proxy) cannot distinguish between genetic and non-genetic components of effect (60), whereas, here, we estimate the contribution of the genetic component. Second, TWAS allows directional interpretation of observed associations that are not possible when correlating tumor gene expression and recurrence. For instance, prior studies report *CCNB2* is upregulated in triple-negative breast cancers (TNBC) but were unable to determine whether increased *CCNB2* expression contributes to development or maintenance of TNBC or is part of the molecular response to cancer progression (61,62). By contrast, GReX is a function of only genetic variation. As such, we can confidently rule out that differences in *CCNB2* GReX are not direct consequences of subtype (and by extension recurrence); however, our observed associations of *CCNB2* GReX and subtype suggest a potential directional relationship for further study. Thus, TWAS allows a directional, causal interpretation, subject to effective control for population stratification, minimal horizontal pleiotropy, and assumptions of independent assortment of alleles (24,25).

Our TWAS-gene and subtype associations among WW are consistent with literature on the association between tumor (i.e., genetic and non-genetic) expression of our TWAS-genes and subtype. Prior investigations in cohorts of primarily European ancestry have reported that *MCM10*, *FAM64A*, and *CCNB2* expression is higher in ER-negative compared to ER-positive tumors (61-63). In studies that

compared triple-negative and non-triple negative subtypes, higher *MCM10*, *FAM64A*, and *CCNB2* expression was detected in triple-negative breast cancer (61,62). Histologically, HER2-enriched and Basal-like subtypes are typically ER-negative, and triple-negatives are similar to Basal-like subtypes (9,64). Moreover, our findings among WW that GReX of *PCSK6* and *VAV3* associated with LumA subtype and LumA-specific gene expression are also consistent with previous results of *PCSK6* and *VAV3* upregulation in ER-positive subtypes (65,66). Importantly, our associations suggest directional mechanisms: from germline variation, to GReX of TWAS-gene, and ultimately, to subtype.

Presently, little is known about germline genetic regulation of PAM50 tumor expression. In CBCS, we found that tumor expression of most PAM50 genes is not *cis*-heritable (18). Instead, observed TWAS-gene and PAM50 gene expression associations may implicate *trans*-gene regulation of the PAM50 signature. For instance, we found that *VAV3* GReX is significantly positively associated with tumor expression of *BAG1*, *FOXA1*, *MAPT*, and *NAT1* and nominally with increased tumor *ESR1* expression, all of which are Luminal A-specific genes. Such *trans*-genic regulation signals, especially in the case of *ESR1*, pose significant clinical and therapeutic implication if confirmed under experimental conditions. For example, *VAV3* activates *RAC1* which upregulates *ESR1* but such mechanistic evidence is sparse for other putative TWAS-gene to PAM50 gene associations (67,68). More generally, two of the TWAS-genes among WW have been found to activate transcription factors; *FAM64A* enhances oncogenic nuclear factor-kappa B (NF-κB) signaling while both FAM64A and *PCSK6* activate oncogenic *STAT3* signaling (69-71).

Differences in the number and effect of identified TWAS-genes by race point to factors that warrant further investigation: (1) potential greater contribution of *trans*-regulation in tumor gene expression in BW (methods for capturing *trans*-regulation in gene expression predictive models are not as well-developed as those for *cis*-regulation) (18) and (2) potential racial differences in tumor methylation and somatic alternations, which were not assayed in CBCS (18,72-77). These factors should be investigated further as transcriptomic and epigenomic datasets for racially-diverse cohorts of breast cancer patients become available. Interestingly, we found *MMP1* GReX has divergent associations with ROR across race. There

are a few potential explanations. First, the range of *MMP1* GReX was manifold among WW than BW, suggesting sparser *cis*-eQTL architecture of *MMP1* in BW and more influence from *trans*-acting signals. Potential differences in influence of germline genetics on tumor expression and ROR by race could be an artifact of divergent somatic or epigenetic factors that CBCS has not assayed (74-77). Second, while studies generally report that *MMP1* tumor expression is higher in triple-negative and Basal-like breast cancer, one study reported that *MMP1* expression in tumor cells does not significantly differ by subtype (78-80). Instead, Bostrom *et al*. reported that *MMP1* expression differs in stromal cells of patients with different subtypes (80). There is evidence to suggest that tumor composition, including stromal and immune components, may influence breast cancer progression in a subtype-specific manner. Future studies should consider expression predictive models that integrate greater detail on tumor cell-type composition to disentangle potential race-specific tumor composition effects on race-specific TWAS associations (81,82).

There are a few limitations to this study. First, as CBCS used a Nanostring nCounter probeset for mRNA expression quantification of genes relevant for breast cancer, we could not analyze the whole human transcriptome. While this probeset may exclude several *cis*-heritable genes, CBCS contains one of the largest breast tumor transcriptomic datasets for Black women, allowing us to build well-powered race-specific predictive models, a pivotal step in ancestry-specific TWAS. Second, CBCS lacked data on somatic amplifications and deletions, inclusion of which could enhance the performance of predictive models of tumor expression (83). Third, as recurrence data was collected in a small subset with few recurrence events, we were unable to make a direct comparison between CRS and recurrence results, which may affect clinical generalizability. However, to our knowledge, CBCS is the largest resource of PAM50-based CRS data.

Our analysis provides evidence of race-specific putative germline associations to CRS, mediated through associations between genetically-regulated tumor expression of TWAS-genes and PAM50 expressions and subtype. This work underscores the need for larger and more diverse cohorts for genetic epidemiology studies of breast cancer. Future studies should consider subtype-specific genetics (i.e.,

stratification by subtype in predictive model training and association analyses) to elucidate heritable gene expression effects on breast cancer outcomes both across and within subtype, which may yield further hypotheses for more fine-tuned clinical intervention.

ACKNOWLEDGEMENTS

We thank the Carolina Breast Cancer Study participants and volunteers. We also thank Colin Begg, Jianwen Cai, Katherine Hoadley, Yun Li, and Bogdan Pasaniuc for valuable discussion during the research process. We thank Erin Kirk and Jessica Tse for their invaluable support during the research process. We thank the DCEG Cancer Genomics Research Laboratory and acknowledge the support from Stephen Chanock, Rose Yang, Meredith Yeager, Belynda Hicks, and Bin Zhu. We also acknowledge the iCOGs Consortium for their publicly available GWAS summary statistics.

FUNDING

This work was supported by Susan G. Komen® for the Cure for CBCS study infrastructure. Funding was provided by the National Institutes of Health, National Cancer Institute P01-CA151135, P50-CA05822, and U01-CA179715 to AFO, CMP, and MAT. AP is supported by T32ES007018. MIL is supported by R01-HG009937, R01-MH118349, P01-CA142538, and P30-ES010126. The Translational Genomics Laboratory is supported in part by grants from the National Cancer Institute (3P30CA016086) and the University of North Carolina at Chapel Hill University Cancer Research Fund. Genotyping was done at the DCEG Cancer Genomics Research Laboratory using funds from the NCI Intramural Research Program. This content is solely the responsibility of the authors and does not necessarily represent the official views of the National Institutes of Health. The funder had no role in study design, data collection, analysis or interpretation, or writing of the manuscript.

Funding for BCAC and iCOGS came from: Cancer Research UK [grant numbers C1287/A16563, C1287/A10118, C1287/A10710, C12292/A11174, C1281/A12014, C5047/A8384, C5047/A15007, C5047/A10692, C8197/A16565], the European Union's Horizon 2020 Research and Innovation

Programme (grant numbers 634935 and 633784 for BRIDGES and B-CAST respectively), the European Community's Seventh Framework Programme under grant agreement n° 223175 [HEALTHF2-2009-223175] (COGS), the National Institutes of Health [CA128978] and Post-Cancer GWAS initiative [1U19 CA148537, 1U19 CA148065-01 (DRIVE) and 1U19 CA148112 - the GAME-ON initiative], the Department of Defence [W81XWH-10-1-0341], and the Canadian Institutes of Health Research CIHR) for the CIHR Team in Familial Risks of Breast Cancer [grant PSR-SIIRI-701]. All studies and funders as listed in Michailidou K *et al* (2013 and 2015) and in Guo Q et al (2015) are acknowledged for their contributions.

AVAILABILITY OF DATA AND MATERIALS

Expression data from CBCS is available on NCBI GEO with accession number GSE148426. CBCS genotype datasets analyzed in this study are not publicly available as many CBCS patients are still being followed and accordingly CBCS data is considered sensitive; the data is available from M.A.T upon reasonable request. Supplementary Data includes summary statistics for eQTL results, tumor expression models, and relevant R code for training expression models in CBCS and are freely available at https://github.com/bhattacharya-a-bt/CBCS_TWAS_Paper/. R code for analyses provided in this paper are available at https://github.com/APUNC/CBCS---Risk-of-Recurrence-Paper. iCOGs summary statistics are available online at http://bcac.ccge.medschl.cam.ac.uk/bcacdata/icogs-complete-summary-results.

FIGURE LEGENDS

Figure 1. *Schematic of study analytic approach.* A) In CBCS, constructed race-stratified predictive models of tumor gene expression from *cis*-SNPs. B) In CBCS, imputed GReX at individual-level using genotypes and tested for associations between GReX and CRS in race-stratified linear models; only GReX of genes with significant *cis*-h^2 and high cross validation performance (R^2 > 0.01 between observed and predicted expression) considered for race-stratified association analyses. C) Follow-up analyses on TWAS-genes (i.e., genes whose GReX were significantly associated with CRS at FDR <0.10). In race-stratified models, PAM50 SCCs and PAM50 tumor expressions were regressed against TWAS-genes under a Bayesian multivariate regression and multivariate adaptive shrinkage approach.

Figure 2. *Permutation tests and associations between TWAS-genes and CRS for WW and BW***.** A) Effect estimates correspond to change in ROR-S, Proliferation score, and ROR-P per one standard deviation increase in TWAS-gene expression (i.e., one standard deviation increase in GReX of gene). Triangle denotes WW and circle denotes BW. B) Boxplots correspond to null distributions (shuffled GReX-sample labels on left, random set of genes on right) of covariates residualized-R2 for regressions of CRS on

TWAS-genes. Null distributions are provided for 10,000 permutations of the GReX-sample labels and 10,000 random sets of genes. Dashed horizontal lines correspond to observed covariates residualized-R2.

Figure 3. *Associations between TWAS-genes and PAM50 SCCs and gene expression.* A) Among AA (top) and WW (bottom), associations between TWAS-genes and PAM50 SCCs using Bayesian multivariate regression and multivariate adaptive shrinkage. Effect estimates show change in SCCs (range -1 to 1) for one standard deviation increase in TWAS-gene GReX. Circle, triangle, and square denote corresponding LFSR intervals for effect sizes. B) Heatmap of change in $\log_2$ normalized PAM50 tumor expression for one standard deviation increase in TWAS-GReX. *, **, *** denote FDR intervals for effect sizes.

TABLES

Table 1: *Race-specific associations between germline-regulated tumor gene expression (GReX) of TWAS-genes and CRS*. Effect estimates correspond to change in CRS per 1 standard deviation increase in GReX, adjusted for age, estrogen receptor status, stage, and CBCS study phase. 95% confidence intervals of effect sizes are provided. All TWAS-gene and CRS pairs shown here showed overall association FDR-adjusted $P < 0.10$, and FDR-adjusted permutation $P < 0.05$ (across 5,000 permutations of the SNP-gene weights). We also provide signatures that include these genes as reference (**Supplementary Table S1**).
