#### 60 Abstract

61 Syphilis is an important sexually transmitted infection caused by the bacterium Treponema 62 pallidum subspecies pallidum. The last two decades have seen syphilis incidence rise in 63 many high-income countries, yet the evolutionary and epidemiological relationships that 64 underpin this are poorly understood, as is the global *T. pallidum* population structure. We 65 assembled a geographically and temporally diverse collection of clinical and laboratory 66 samples comprising 726 T. pallidum genomes. We used detailed phylogenetic analysis and 67 clustering to show that syphilis globally can be described by only two deeply branching 68 lineages, Nichols and SS14. We show that both of these lineages can be found circulating 69 concurrently in 12 of the 23 countries sampled. To provide further phylodynamic resolution 70 we subdivided Treponema pallidum subspecies pallidum into 17 distinct sublineages. 71 Importantly, like SS14, we provide evidence that two Nichols sublineages have expanded clonally across 9 countries contemporaneously with SS14. Moreover, pairwise genome 72 73 analysis showed that recent isolates circulating in 14 different countries were genetically 74 identical in their core genome to those from other countries, suggesting frequent exchange through international transmission pathways. This contrasts with the majority of samples 75

collected prior to 1983, which are phylogenetically distinct from these more recently isolated sublineages. Bayesian temporal analysis provided evidence of a population bottleneck and decline occurring during the late 1990s, followed by a rapid population expansion a decade later. This was driven by the dominant *T. pallidum* sublineages circulating today, many of which are resistant to macrolides. Combined we show that the population of contemporary syphilis in high-income countries has undergone a recent and rapid global expansion.

83

#### 84 Introduction

85 Syphilis, caused by the bacterium Treponema pallidum subspecies pallidum (TPA), is a 86 prevalent sexually transmitted infection which can cause severe long-term sequelae when left untreated. Historically, syphilis is commonly believed to have caused a large epidemic 87 across Renaissance Europe, having previously been absent or unrecognised<sup>1,2</sup>. Although 88 accurate dating of the most recent common ancestor of TPA is still the subject of debate $^{3-6}$ , 89 90 it is suggested that the strains of TPA that persist in the human population to this day can be 91 traced back to that introduction into Western Europe approximately 500 years ago, and subsequently disseminated globally<sup>3,4,6</sup>. 92

93

94 Following the introduction of effective antibiotics after World War II, syphilis incidence fluctuated<sup>7</sup> without disappearing, until the 1980s and 1990s during the HIV/AIDS crisis when 95 disease incidence declined markedly<sup>8</sup>, linked to community wide changes in sexual 96 behaviour, shifting of affected populations, AIDS-related mortality and widespread 97 antimicrobial prophylaxis of HIV infected populations. However, since the beginning of the 98  $21^{st}$  century, there has been a substantial resurgence in syphilis incidence<sup>9-13</sup>. In many 99 countries, this has been associated with populations of men who have sex with men (MSM) 100 engaging in high risk sexual activity<sup>11,14</sup>. Transmission between MSM and heterosexuals is a 101 particular concern due to the risk of *in utero* transmission to the foetus, leading to 102 103 congenital syphilis<sup>15</sup>.

104

105 Previous genomic analyses of TPA genomes have described two deep branching phylogenetic lineages 'SS14' and 'Nichols'<sup>3</sup>. SS14-lineage strains represent the vast majority 106 of published genomes<sup>4</sup>, and phylogenetic analysis showed that the origins of the SS14-107 lineage can be traced back to the 1950s<sup>3</sup>, followed by subsequent expansion of sublineages 108 occurring during the 1990s<sup>4</sup>. Our understanding of Nichols-lineage is predominantly limited 109 to laboratory strains from the USA, with relatively few clinical strains sequenced<sup>4,16</sup>. 110 However, most TPA genomes published to date originate from the USA<sup>4</sup>. Western 111 Europe<sup>3,4,16,17</sup> and China<sup>18,19</sup>, and our understanding of the true breadth of diversity of TPA is 112 113 incomplete<sup>20</sup>. This is partly explained, by the fact it has not been possible to culture TPA. outside of a rabbit until recently<sup>21</sup>, and also explains why our view of the diversity of syphilis 114 samples predating the 21<sup>st</sup> century is even more limited. 115

116

117 In this multicentre collaborative study, we used direct whole genome sequencing to 118 generate a global view of contemporary syphilis from patients in Africa, Asia, the Caribbean, 119 South America and Australia sampled between 1951 and 2019. Our dataset also includes a 120 detailed analysis of the 'within-country' variation seen in TPA genomes in North America 121 and Europe. We present evidence of globally spanning transmission networks with identical 122 strains found in dispersed countries, indicating that, based on our data, TPA is essentially 123 panmictic. Furthermore, we show that this genetic homogeneity is the result of a rapid and 124 global expansion of TPA sublineages occurring within the last 30 years following a population bottleneck. This means the TPA population infecting patients in the 21<sup>st</sup> century 125 is not the same as that infecting patients in the 20<sup>th</sup>. 126

127

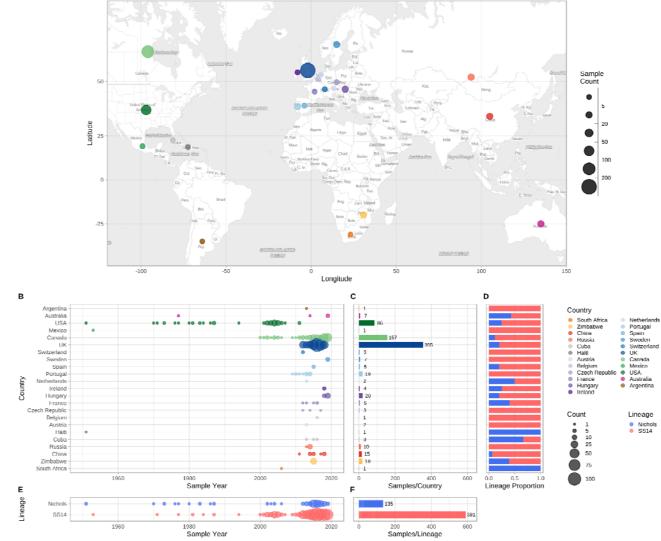

#### 128 **Results**

# Describing the global population structure of *Treponema pallidum* subspecies*pallidum*

We performed targeted sequence-capture whole genome sequencing on residual genomic DNA extracted from diagnostic swabs taken from TPA PCR positive syphilis patients, and on TPA strains previously isolated in rabbits. We combined these data with 133 previously published genomes<sup>3,4,17–19,22–25</sup>. After assessment for genome coverage and quality, we had a total of 726 genomes with >25% of genome positions at >5X coverage (mean 82%, range 25-97%), sufficient for primary lineage classification. This dataset included 577 new genomes sequenced directly from clinical samples, and 16 new genomes sequenced from samples passaged in rabbits.

139

140 Our dataset includes 23 countries (range 1-355 genomes per country; Figure 1A, 1C), 141 including previously poorly or unsampled regions including Africa (South Africa (n=1) and 142 Zimbabwe (n=18)), Scandinavia (Sweden, n=7), Central Europe (Hungary, n=20), Central Asia 143 (Tuva Republic, Russia, n=10) and Australia (n=5), as well as substantially increasing the 144 sampling from North America (Canada, n=157; United States, n=86) and Western Europe 145 (Spain, n=5; Belgium, n=1; Ireland, n=4; the United Kingdom, n=355). Due to a lack of long 146 term archived samples, 96.0% (n=697) of samples were collected from 2000 onwards 147 (Figure 1B, 1E). Samples collected prior to 2000 (n=29) were passaged in the in vivo rabbit 148 model (Supplementary Data 1), whereas most samples collected from 2000 onwards 149 (89.8%, 626/697) were sequenced directly from clinical samples.

50

A- Map of sampled countries for 726 partial (>25% of genome positions) genomes. Circle size corresponds 52 to total number of genomes (binned into categories), and colour corresponds to country. Country ;3 ;4 coordinates used are the country centroid position, apart from Russia (where the centroid for the Tuva 55 Republic is used) and Mexico (where the location of Mexico City is used). Map tiles by Stamen Design (CC-56 BY 3.0), map data by OpenStreetMap (ODbl). B- Temporal distribution of samples by country. Size of circle indicates number of samples for that year. Three samples from Baltimore (USA) had uncertain sampling 57 dates (1960-1980) and were set to 1970 for plotting dates (1B, 1E). Genomes derived from passaged 58 ;9 variants of the Nichols-1912 isolate or with uncertain collection dates are not shown in plotted timeline 50 (1B, 1E). C-Total count of samples by country. D- Relative proportion of country samples corresponding to 51 each TPA lineage (where only one sample was present per country, shows the lineage this corresponds to). 52 E-Temporal distribution of the samples by TPA lineage. F- Total count of samples by TPA Lineage.

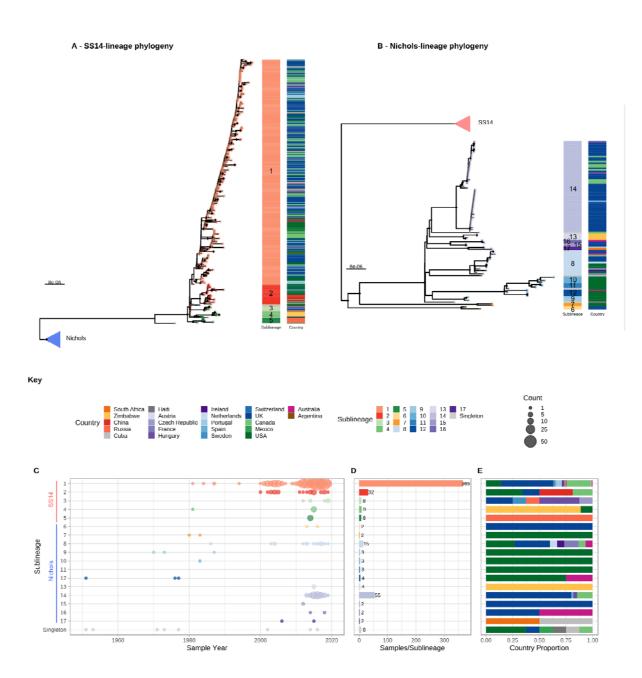

164 Phylogenetic analysis assigned all genomes into one of two deeply branching lineages 165 ("Nichols" or "SS14") (Supplementary Figure 1). Looking across all well sampled countries 166 (Figure 1C, 1D), from the first detection of the modern SS14-lineage (excluding the outlying 167 1953 Mexico A strain) in the 1970s, we consistently see both lineages circulating broadly through until 2019 (Figure 1B, 1E). More specifically 81.3% (n=590) of genomes belonged to 168 169 the SS14-lineage and 18.7% (n=136) to the Nichols-lineage, and in the 12/23 countries 170 where both lineages were present, 80.3% (544/677, median per country 75.3%, range 33.3-171 93.3%) were SS14-lineage (Figure 1D, 1F). In the 11 countries showing only a single lineage, 172 most had three or fewer samples, the notable exceptions being Portugal (n=19), Sweden 173 (n=7) and Russia (n=10) (Figure 1C).

174

#### 175 Fine scaled analysis of SS14- and Nichols- lineage phylogenies

176 To answer finer scaled evolutionary questions, we filtered our dataset to focus on the 528 177 genomes with >75% genome sites at >5X (genome length 1,139,569 bp, mean % sites 92.9%, 178 range 75.1–96.9%) and a mean coverage of 111X (range 11X–727X). This filtered dataset 179 comprised 401 new and 127 published genomes (Supplementary Data 1), but excluded the 180 only sample from Belgium, leaving 22 countries in the analysis. After excluding 19 regions of recombination and genomic uncertainty due to gene orthology or repetitive regions<sup>3,4,6</sup>, we 181 used Gubbins<sup>26</sup> to infer a further 19 regions of putative recombination (see Methods and 182 Supplementary Data 2 for details). We refer to the resulting masked sequence alignment as 183 184 the core genome and used it to infer a whole genome maximum likelihood phylogeny using IQ-Tree<sup>27</sup> (Supplementary Figure 2). To define sublineage clusters we used 100 185 bootstrapped trees as independent inputs to rPinecone<sup>28</sup> with a 10 SNP threshold, and 186 187 evaluated their consistency using hierarchical clustering (Supplementary Figure 3). We 188 found broad support for the Nichols sublineages across all conditions evaluated, but some 189 parts of the SS14-lineage phylogeny were less well supported. To focus on the more stable 190 sublineages, we required that at least 5% of the bootstrap replicates supported a cluster. 191 Using this approach, we defined 17 sublineages and 8 singleton strains across both SS14-192 and Nichols-lineages (SS14: 426 genomes divided into 5 sublineages and 4 singletons; 193 Nichols: 102 genomes divided into 12 sublineages and 4 singletons; Figure 2; Supplementary 194 Figures 2, 4, 5).

196 From Figure 2 it is apparent that the phylogeny of SS14-lineage is dominated by SS14 197 sublineage 1 (n=365), comprised of closely related genomes present in 18 countries and six 198 continental groupings (Asia, Caribbean, Europe, North America, Oceania, and South 199 America). The oldest example of sublineage 1 was collected in 1981 (TPA USL-SEA-81-3, 200 Seattle USA), and the most recent samples were from 2019 (Figure 2C). Sublineage 2 (n=32; 201 Figure 2E, Supplementary Figure 4) contained samples from Canada, China, the UK and the 202 USA. In a previous analysis<sup>4</sup>, we manually divided this sublineage into two groups (one from 203 China, one from the USA), based on temporal and geospatial divergence, and the 204 independent evolution of different macrolide resistance alleles. However, by adding new genomes (Supplementary Figure 4), we now see that even the original cluster of samples 205 206 from China is interspersed with genomes from the UK (n=1) and Canada (n=4), indicating 207 that this is not a geographically restricted group.

209 Figure 2. Fine scaled analysis of 528 high quality (>75% reference sites) TPA genomes and 210 sublineages. A- Recombination masked WGS phylogeny, highlighting the SS14-lineage (n=426). B-211 Recombination masked WGS phylogeny, highlighting the Nichols-lineage (n=102), including four 212 outlying genomes (sublineages 6 & 7). For A and B, coloured strips show sublineage and country; 213 Tree tips show sublineage. Coloured triangle indicates node position of collapsed sister lineage. UF 214 Bootstraps >=95% are marked with black node marks. C-Temporal distribution of samples by 215 sublineage (unrelated singleton genomes are grouped together). D- Total count of samples by 216 sublineage. E- Relative proportion of each sublineage samples corresponding to country.

217 The 12 2015 Zimbabwean genomes in our study formed two distinct clades, one nested 218 within SS14-lineage (sublineage 4, n=8, also containing a single distantly related sample 219 from the USA 1981, TPA USL-SEA-81-8), the other within Nichols-lineage (sublineage 13, 220 n=4) and exclusively found in Zimbabwe. We also examined 10 genomes collected in the 221 Tuva Republic, central Russia in 2013/2014, and these were distributed between three 222 different SS14 sublineages (1, 3, 5). Sublineage 5 was found only in Tuva, whilst sublineage 3 223 was found throughout Europe (Czech Republic, Hungary, Sweden and the UK; Figure 2E, 224 Supplementary Figure 4), with the remaining sample from Russia belonging to the highly 225 expanded global SS14 sublineage 1.

226

227 Consistent with previous studies<sup>3,4,16</sup> Nichols-lineage strains were genetically more diverse, 228 with longer branch lengths and higher nucleotide diversity than SS14-lineage (Nichols 229  $\pi$ =3.2x10<sup>-5</sup>, SS14  $\pi$ =6x10<sup>-6</sup>), reflecting the predicted age of lineage diversification. However, 230 our increased sampling also revealed two recent clonal expansions within the Nichols-231 lineage: sublineage 14 (n=55), comprising samples from Canada, Hungary, Spain and the UK 232 (Figure 2E) and sublineage 8 (n=15) comprising samples from the Australia, Canada, France, 233 Ireland, the Netherlands, the UK, and the USA (Supplementary Figure 5).

234

In addition to observing evidence of recent clonal expansions we also show greater resolution of Nichols-lineage diversity, identifying two new samples from UK patients (PHE130048A, PHE160283A, collected in 2013 and 2016 respectively) which occupy positions basal to all Nichols-lineage strains (Supplementary Figure 5). Indeed, this analysis suggested the most recent common ancestor of this sublineage was very close to the root of all TPA.

241

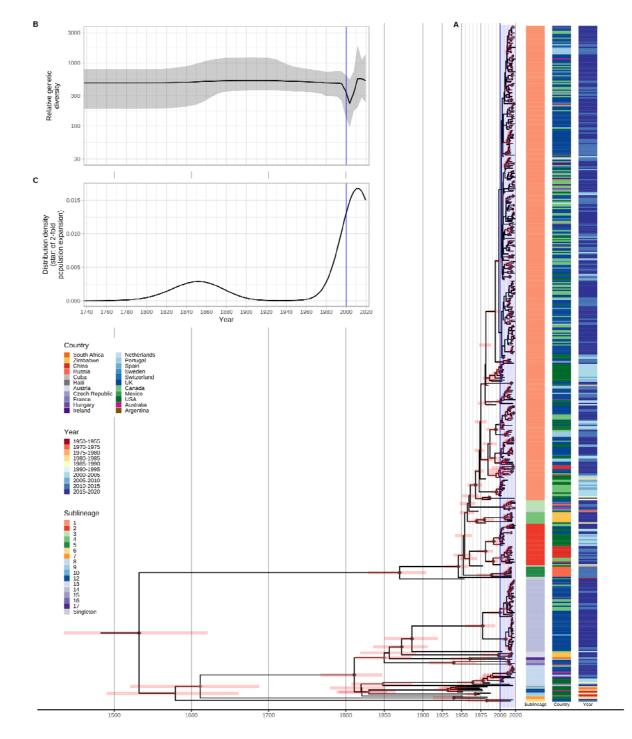

242 Multiple derivatives of the highly passaged prototype Nichols-lineage strain (denoted 243 Nichols-1912) isolated in 1912 were included in our analysis (Nichols\_v2, Seattle\_Nichols, 244 Nichols\_Houston\_E, Nichols\_Houston\_J, and Nichols\_Houston\_O). Figure 2B 245 (Supplementary Figure 6) shows that derivatives of Nichols-1912 fall within a distinct clade 246 which also includes independently collected contemporaneous clinical samples (some with

minimal passage through the rabbit model), including a sample (TPA\_AUSMELT-1) collected 247 in Australia in 1977<sup>29</sup>. This clade could be subdivided into four sublineages (9, 10, 11, 12) 248 249 and one singleton. Notably, the last sample belonging to this clade was collected in 1987 250 (TPA USL-Phil-3). Hence, within our sampling framework this appears to be an example of a 251 historic lineage becoming extinct. More broadly, we note that although this cluster of both 252 clinical and laboratory strains were all passaged to varying degrees through the rabbit, other samples passaged in the rabbit were distributed throughout the phylogeny and were 253 254 present in 9/17 sublineages (Supplementary Figure 7).

255

#### 256 Temporal analysis of population dispersal

257 To infer temporal patterns within the global phylogeny, we performed Bayesian phylogenetic reconstruction using BEAST<sup>30</sup> under a Strict Clock model with a Bayesian 258 259 Skyline population distribution. We excluded 8 samples from strains known to be heavily 260 passaged or with uncertain collection dates from the previous dataset of 528, giving a 261 dataset of 520 samples and 883 variable sites. We inferred a median molecular clock rate of 262  $1.28 \times 10^{7}$  substitutions/site/year (95% Highest Posterior Density (HPD)  $1.07 \times 10^{7} - 1.48$  $x10^{-7}$ ), equivalent to one substitution/genome every 6.9 years, consistent with recent 263 analyses<sup>4,6</sup>. 264

55

Figure 3. Bayesian maximum credibility phylogeny of 520 TPA genomes shows population contraction during the 1990s, followed by rapid expansion from the early 2000s onwards. A- Time-scaled phylogeny of 520 TPA genomes. Node points are shaded according to posterior support (black ≥96%, dark grey >91%, light grey >80%). Red bars on nodes indicate 95% Highest Posterior Density intervals. Blue line and shaded area highlight post-2000 expansion of lineages. B- Bayesian Skyline plot of genetic diversity shows small population expansion and contractions during the 19th and 20th Centuries, followed by a sharp decline and rapid re-emergence during the 1990s and 2000s. C- Posterior distribution of start dates for a 2-fold

- v3 expansion above skyline mean shows strong support for expansion after 1990 in 68.6% (9263/13503) of
- '4 trees.

275 Within the global TPA phylogeny (Figure 3A), we observed several patterns of genomic 276 dispersal. The first reflects the separation of the Nichols- and SS14-lineages (median date in 277 our analysis 1534, 95% Highest Posterior Density 1430-1621), the subject of much previous analysis<sup>3,4,6</sup>. These data also showed that the common ancestor of these lineages is 278 279 separated from recent samples by long phylogenetic branches and an absence of older 280 ancestral nodes, suggesting unsampled historical diversity, and that most contemporary TPA 281 descend from much more recent ancestral nodes. We previously dated the common 282 ancestors for clonal expansions of 9 SS14 sublineages between the 1980s and early 2000s<sup>4</sup>. 283 With this expanded dataset, we focussed on the ancestral nodes leading to the major 284 clonally expanded sublineages 1, 2, 8 and 14, each having at least 15 samples.

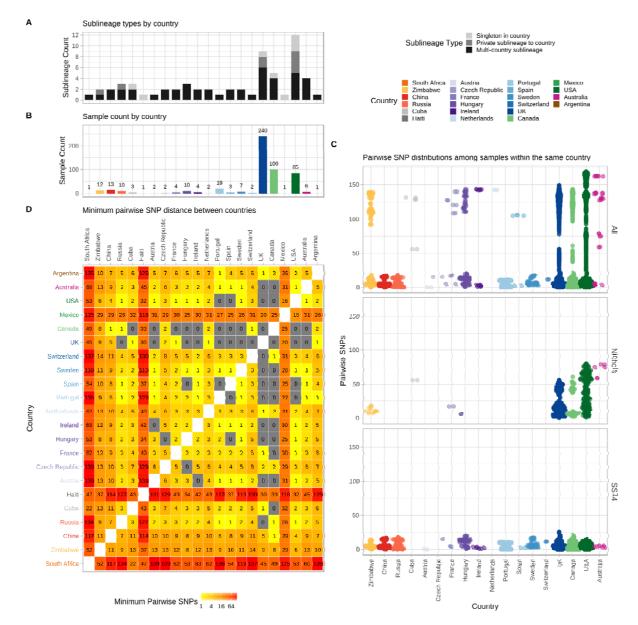

285

286 Next, we used Bayesian Skyline analysis to determine the relative genetic diversity over 287 different time periods in the phylogeny (Figure 3B), showing a very sharp decline during the 288 1990s and 2000s, followed by an equally sharp rise that continued until present day. To test 289 the statistical support for this expansion, we extracted the proportion of trees in the 290 posterior distribution supporting a >2-fold population expansion above the population 291 mean (68.6%, 9263/13503 trees), and plotted the distribution of expansion start dates 292 (Figure 3C) (median date 2011). We further tested the proportion of trees supporting a 2-293 fold population decline between 1990-2015 (90.7%, 12248/13503 trees, median date 2000) 294 and a 2-fold population expansion between 1990-2015 (59.0%, 7966/13503 trees, median 295 date 2012) (Supplementary Figure 8). These findings were also apparent in SS14 sublineages 296 1 and 2 (Supplementary 9) but not for Nichols sublineage 8. We had insufficient temporal 297 signal to repeat this analysis on multi-country expanded Nichols sublineage 14 298 (Supplementary Figure 10).

299

#### 300 Global sharing of sublineages and identical strains

To further understand the patterns of recent population expansion we sought evidence of sharing of sublineages among countries, classifying sublineages as singletons (n=8), private to a country (n=8), or multi-country (n=9), and found that 20/22 countries contained at least one multi-country sublineage (Figure 4A, Supplementary Figure 11). We inferred pairwise 305 SNP distances for genomes within and between each country (Figure 4C, 4D), and where 306 there was more than one sample (n=18), we found fewer than 26 (SS14-lineage) and 80 307 (Nichols-lineage) pairwise SNPs separating genomes within any one country (Figure 4C), 308 illustrating the close genetic relationships between samples (particularly SS14-lineage). We 309 also found very low genetic distance between paired samples from different countries, with 310 27 country pairings (14 countries) showing zero core genome pairwise SNPs (Figure 4D). In 311 particular Canada, UK and USA, with the highest sampling (Figure 4B), showed the most zero 312 pairwise interactions with other countries (Figure 4D). Therefore, we cannot rule out similar 313 transmission events occurring between other countries. We compared pairwise SNP 314 distances with geographical distance between country centroids. Although we found a 315 moderate correlation for Nichols-lineage (Pearson's correlation 0.49, p<0.001), this was 316 lower for SS14-lineage (0.31, p<0.001) and for the four largest multi-country sublineages 317 (sublineage 1, 0.09, p<0.001; sublineage 2, 0.43, p<0.001; sublineage 8, 0.27, p<0.001; 318 sublineage 14, 0.08, p<0.001) (Supplementary Figure 12). Hence, overall this indicates weak 319 geographical structure for TPA.

320

321 Figure 4. Substantial sharing of closely related strains within and between countries. A- Number 322 of sublineages found per country, classified by sublineage distribution (multi-country=black, private 323 to one country=medium grey, singleton=light grey). B- Total high-quality genomes per country. C-324 Pairwise comparison of SNP distance distributions from samples in each country (where >1 sample), 325 across all samples and within lineages. D- Minimum pairwise SNPs between samples from different 326 countries. All pairwise SNP comparisons exclude comparisons with same samples. Haiti, South 327 Africa and Mexico appear striking outliers in terms of genetic relatedness (D), but this reflects that 328 the Haiti and Mexico samples were collected in the 1950s, and we had only a single genome from 329 these countries.

330 To understand these observations more fully, we focussed on British Columbia (Canada; BC) 331 and England, both of which have experienced a recent rise in syphilis incidence 332 (Supplementary Figure 13A), and for which we had a large number of samples. Included 333 were 84 high quality BC genomes collected by the BC Centre for Disease Control between 334 2000 and 2018. From England, we had 240 high quality genomes from samples taken by the 335 National Reference Laboratory at Public Health England (n=198) and non-referring 336 laboratories in London (n=26), Brighton (n=9), Leeds (n=2) and Manchester (n=5) collected 337 between 2012 and 2018. In BC, SS14 sublineage 1 dominated throughout the 18-year survey 338 period, representing 82% of all BC genomes (Supplementary Figure 13B). In addition, 339 isolated cases of SS14 sublineage 2 were seen in 2000 and 2012 as well as a single Nichols-340 lineage sample (singleton) in 2002 (Supplementary Figure 13B). Then from 2013 onwards, 341 we detected two new Nichols sublineages: Nichols sublineage 8 and sublineage 14. The 342 latter two lineages were also found across USA and Europe (Figure 2E).

343

Both Nichols- and SS14-lineages were consistently present in the English samples between 2012 and 2018. All of the common sublineages (4/4) found in BC were also present in England, as well as 4 additional sublineages (Nichols sublineages 6, 15, 16; SS14 sublineage 3) and one SS14 singleton strain not detected in BC (Supplementary Figure 13B). Sublineage 14, first detected in BC in 2013, was also the most numerous Nichols sublineage in England, but notably was not detected here until 2014.

350

351 Pairwise SNP distances between orthogonal genomes from the same sublineages showed 352 2622 pairwise combinations of BC (n=56) and English samples (n=78) sharing zero pairwise 353 SNPs over the core genome alignment for isolates collected between 2004 and 2019. To 354 understand the effect of temporal distance we compared both the pairwise SNP distance 355 and the pairwise time distance (in years) between genomes from the same sublineage 356 (Supplementary Figure 13D). These data showed that the mean number of years separating 357 identical core genomes was 2.5 years (range 0-15), and the mean temporal distances of 358 identical genomes were similar within BC (2.9 years) and England (1.9 years) and between 359 the two (2.7 years). The number of pairwise SNPs increased with temporal separation across 360 all BC and English genomes from the same sublineage (Pearson's Correlation 0.126,

361 p<0.001), with a mean of 4.9 SNPs (range 0–23) separating genomes from the same year 362 and sublineage, compared to 7.8 SNPs (range 6-11) after 19 years (Supplementary Figure 363 13D). This means that inference of direct patient-to-patient TPA transmission using the core 364 genome will be challenging at the population level, and limit opportunities for real time 365 genomic epidemiology because identical genomes can be separated by many years, and 366 confidence intervals around temporal reconstructions will be broad. In the case of 367 sublineage 14, we first detected this in BC, then the following year in England. Since we had 368 a deeply sampled survey of populations over time for both countries, it seems likely that 369 this represents a novel introduction into BC and England. However, low temporal rates and 370 incomplete sampling, mean this must be interpreted with caution.

371

We also found some rarer sublineages – either as singleton strains, or those private to a single country. Whilst this might be expected in poorly sampled and geographically distant locations, such as Cuba, Haiti, Mexico and Zimbabwe, we found that the majority of private (6/8) and singleton (5/8) sublineages were actually from Canada, the UK or USA (Figure 4A), suggesting deeper sampling elsewhere will also find novel diversity.

377

378 Given our observations of individual sublineage expansion, we investigated whether the 379 expansion could be related to antimicrobial resistance. Overlaying inferred macrolide 380 resistance causing SNPs (A2058G, A2059G) in the ribosomal 23S rRNA gene on these 381 population expansions showed evidence of macrolide resistance in 6/9 multi-country 382 sublineages (Supplementary Figure 14), with the majority of samples being resistant in the 383 largest sublineages 1, 2, 8 and 14. In contrast, only one private sublineage (sublineage 6, 384 n=2) contained a macrolide resistant sample, suggesting that macrolide resistance is 385 potentially linked to expansion in multicountry sublineages.

386

387

## 388 Discussion

Previous attempts to understand the origins of the original syphilis pandemic<sup>3,6,20</sup>, as well as 389 the dynamics of the current  $one^{3,4}$ , have been constrained by the technical difficulty of 390 391 sequencing TPA genomes, as well as relatively small datasets, with limited geographical 392 diversity and sampling biases. In our study, we assembled the most comprehensive and broad ranging collection of syphilis samples from around the world to date, including 393 samples from both the 20<sup>th</sup> and 21<sup>st</sup> century. Despite this, we still find that the TPA 394 395 population consists of just two deep branching lineages, SS14-lineage and Nichols-lineage, 396 with no outlying lineages. We were able to show that these lineages are both globally 397 distributed and, where we have densely sampled, we find the relative proportions of each 398 to be consistent. Although the overall diversity detected within the Nichols-lineage is far 399 greater than that of SS14-lineage, suggesting earlier dissemination, we also found that these 400 two major lineages exhibit similar phylodynamics, with recent sublineage expansions 401 apparent in both lineages. This suggests that both Nichols- and SS14-lineages are capable of 402 exploiting the transmission pathways driving the current syphilis epidemic.

403

404 Amongst our data, we sequenced the first genomes from syphilis patients in Africa, and our 405 analysis shows that these genomes represented novel private sublineages, but their 406 genomic diversity is nested entirely within the existing phylogenetic framework – these TPA 407 genomes are not unusual. Indeed, we even observed the same pattern of Nichols- and SS14-408 lineages both being present in Zimbabwe, suggesting multiple introduction events into 409 Zimbabwe. The same was true for genomes sequenced from Central Russia (Tuva Republic), 410 where the private sublineage 5 represented novel, but entirely unremarkable genomic 411 diversity.

412

In our study, we found that sublineages and closely related samples were more likely to be shared among deeply sampled countries. This suggests that sublineage sharing between countries is high, and deeper sampling of other countries will likely reveal similar patterns of sharing. As sampling depth increased we also found more rare sublineages, notably sublineage 6, representing novel outlying genetic diversity basal to all contemporary 418 Nichols-lineage examples, in 2/240 contemporary UK patients. This suggests that some 419 sublineages may truly be rare, whilst the high frequency of other sublineages could reflect 420 either fitness advantages or epidemiological factors such as infecting patients within 421 particularly high-risk sexual networks, allowing these sublineages to expand more 422 successfully. Singleton or private sublineages could reflect insufficient sampling of a country or region, or sampling biases within a country (e.g. published genomes from Portugal<sup>17</sup> 423 424 came from a single clinic in Lisbon). These sublineages may therefore reflect transmission 425 networks that are either contained within a less internationally mobile demographic, or may 426 reflect transmission networks common in a region that is otherwise poorly sampled (e.g. 427 Africa).

428

429 Our observation that the well-studied Nichols reference genomes (largely derived from or 430 related to the original Nichols-1912 isolate) form an isolated clade, not represented in 431 contemporary TPA, is important. One possible explanation is that these samples form a 432 distinct clade due to convergent evolution in the rabbit model. However, this clade contains 433 samples both extensively and minimally passaged, whilst other samples passaged in rabbits 434 are distributed throughout the broader phylogeny, included in three SS14 sublineages (1, 2, 435 4) and two additional Nichols sublineages (7, 8). This indicates that passage in the rabbit 436 model has not overly affected other parts of the phylogeny. The majority of Nichols-lineage 437 strains collected prior to 1988 belong to this clade, and these samples mostly come from a 438 small group of laboratories in the USA. Therefore, it is also tempting to suggest that this reflects a sampling bias for that time period. However, the phylogenetic placement of 439 TPA AUSMELT-1 within the same clade, isolated in 1977 in Australia<sup>29</sup>, and independently 440 441 cultured and sequenced, contradicts this hypothesis, and may suggest that this clade 442 represents the dominant TPA of the period. The complete absence of related genomes in 443 contemporary sampling could represent a decline to becoming a rare or even extinct lineage 444 and therefore implies that the Nichols reference strain is not representative of 445 contemporary syphilis, or even contemporary Nichols-lineage strains.

446

447 Our data show that for some sublineages, modern syphilis is a truly global disease, with448 shared lineages, sublineages and indeed nearly identical strains all over the world. The large

expansions of highly related genomes, in particular sublineage 1, represent the bulk of sequenced genomes in our dataset, and the widespread sharing of major lineages suggests we have sampled from a series of globally contiguous sexual networks, making contemporary syphilis effectively panmictic.

453

454 Furthermore, we find evidence of a striking change in the genetic diversity and effective 455 population size of TPA genomes, suggestive of a possible population bottleneck occurring 456 between the late 1990s and early 2000s. This was followed by a rapid expansion of certain 457 sublineages, leading to the contemporary TPA population structure. This bottleneck, 458 potentially a consequence of post-HIV safe sex messaging, persistent antimicrobial 459 prophylaxis in at risk HIV positive populations, and possibly HIV-associated mortality, 460 appears to have led to a striking duality in the TPA dominating populations before and after. 461 The rapid expansion may be attributed to a relaxation of sexual behaviour following the 462 widespread introduction of highly active antiretroviral therapy. Notably, although macrolide 463 resistance was not universally distributed throughout the phylogeny or present in all 464 sublineages, most of the multi-country sublineages were largely macrolide resistant, and this could also have played a role through off-target effects, e.g. during treatment of other 465 (particularly sexually transmitted) infections<sup>31</sup>. Azithromycin and other macrolides are no 466 467 longer recommended treatments at any stage of syphilis in the European syphilis management guidelines<sup>32</sup>. 468

469

There have been some documented reports of clinically diagnosed syphilis caused by *Treponema pallidum* subspecies *endemicum* (TEN)<sup>33,34</sup>. In our study, most novel genomes were clinically diagnosed and confirmed by diagnostic PCRs that do not discriminate between subspecies, yet we found only TPA. Therefore, although we cannot rule out that TEN causes syphilis due to the limits of our sampling framework, our data suggest TEN is not a major contributor to the burden of syphilis in any of our well sampled countries.

476

477 Our study has a number of limitations. Our samples were collected in an opportunistic
478 manner, using residual samples available in regional or national archives. Since our sampling

479 coverage is uneven, with some countries either missing or under-sampled, it was not 480 possible to infer the direction of transmission between countries. Nevertheless, we provide 481 a snapshot of strains from Africa, Asia and South America, all of which overlap with the 482 genetic diversity of our more deeply sampled regions (North America and Europe), 483 suggesting we have captured key global lineages. We also show that even deeply sampled 484 countries can harbour rare sublineages, and it is therefore likely that future studies will 485 reveal further novel diversity. We were constrained in our ability to obtain and sequence 486 older samples from prior to the widespread adoption of molecular diagnostics in the early 487 2000s, and this is largely influenced by the difficulty in isolating new strains prior to the recent development of *in vitro* culture<sup>21</sup>, and the lack of, and long-term storage of clinical 488 489 swabs. Most (but not all) older strains come from the USA, and this could mean that we do 490 not accurately reflect the global population structure prior to 2000.

491

492 Despite this our data show the T. pallidum infecting patients today is not the same T. 493 pallidum infecting patients even 30 years ago - ancestral sublineages appear to have 494 become extinct, being replaced by new sublineages that have swept to dominance across 495 the globe with the dramatic upswing in syphilis cases in the US, UK, and other Western 496 European countries, which were heavily sampled in our study. That such a bottleneck is 497 linked to HIV-related behavioural change during the 1990s, rather than the introduction of 498 antibiotics after the Second World War, further supports the importance of sexual 499 behaviour in transmission dynamics. In future work, it would be interesting to integrate 500 epidemiological evidence of sexual networks in purpose designed cohort studies to explore 501 this further.

502

## 503 Methods

504 <u>Samples</u>

505 Ethical approval for all clinical samples was granted by the London School of Hygiene and

506 Tropical Medicine Observational Research Ethics Committee (REF#16014) and the National

507 Health Service (UK) Health Research Authority and Health and Care Research Wales (UK;

508 19/HRA/0112).

509

510 Novel samples from Australia (Brisbane, Melbourne), Belgium (Antwerp), Canada (Alberta, 511 British Columbia), Hungary (National collection), Ireland (Dublin), Russia (Tuva Republic), 512 South Africa (Johannesburg), Spain (Barcelona), Sweden (National collection), the UK 513 (National collection), Zimbabwe (3 regions), were sequenced directly from genomic DNA 514 extracted from clinical patient swabs or biopsies, typically utilising de-identified residual 515 diagnostic samples which were further pseudonymised before analysis. Additional novel 516 samples from Australia (Melbourne), Haiti and the USA (6 cities) were sequenced from 517 historic freezer archives after prior passage in the rabbit model<sup>4</sup>.

518

519 DNA extracts were quantified by qPCR (TPANIC\_0574) as previously<sup>4</sup>, and grouped into 520 pools of either 32 or 48 with similar (within 2 C<sub>T</sub>) treponemal load with high concentration 521 outlier samples diluted as necessary. We added 4 $\mu$ l pooled commercial human gDNA 522 (Promega) to all samples to ensure total gDNA > 1 $\mu$ g/35 $\mu$ l, sufficient for library prep.

523

#### 524 <u>Sequencing</u>

525 Extracted genomic DNA was sheared to 100-400 bp (mean distribution 150 bp) using an 526 LE220 ultrasonicator (Covaris Inc). Libraries were prepared (NEBNext Ultra II DNA Library 527 prep Kit, New England Biolabs, Massachusetts, USA) using initial adaptor ligation and 528 barcoding with unique dual indexed barcodes (Integrated DNA Technologies, Iowa, USA). 529 Dual indexed samples were amplified (6 cycles of PCR, KAPA HiFi kit, Roche, Basel, 530 Switzerland), quantified (Accuclear dsDNA Quantitation Solution, Biotium, California, USA), then pooled in preassigned groups of 48 or 32 to generate equimolar pools based on Total 531 532 DNA concentration. 500 ng pooled DNA was hybridised using 120-mer RNA baits (SureSelect Target enrichment system, Agilent technologies; Bait design ELID ID 0616571)<sup>4,35</sup>. Enriched 533 libraries were sequenced on Illumina HiSeq 4000 to generate 150 bp paired end reads at the 534 Wellcome Sanger Institute (Cambridgeshire, UK) as previously described<sup>36</sup>. For one rabbit 535 passaged sample from Melbourne, Australia (TPA AUSMELT-1)<sup>29</sup>, genomic DNA extracted 536

from historically archived tissue lysate was sequenced on Illumina NextSeq 500 (150 bp paired end reads, Nextera DNA Flex libraries) without any prior enrichment to an estimated 1Gb/sample at the Doherty Institute (Melbourne, Australia).

540

#### 541 <u>Sequence analysis and Phylogenetics</u>

542 We filtered Treponema genus-specific sequencing reads using the full bacterial and human Kraken  $2^{37}$  v2.0.8 database (March 2019), followed by trimming with Trimmomatic<sup>38</sup> v0.39 543 544 and downsampling to a maximum of 2,500,000 using seqtk v1.0 (available at https://github.com/lh3/segtk) as previously described<sup>4</sup>. For publicly available genomes, raw 545 sequencing reads were downloaded from the European Nucleotide Archive (ENA) and 546 547 subjected to the same binning and downsampling procedure. For five public genomes (see 548 Supplementary Data 1), raw sequencing reads were not available; for these we simulated 549 150 bp PE perfect reads from the RefSeq closed genomes using Fastaq (available at 550 https://github.com/sanger-pathogens/Fastag).

551

552 For phylogenomic analysis, we mapped *Treponema*-specific reads to a custom version of the 553 SS14 v2 reference genome (NC 021508.1), after first masking 12 repetitive Tpr genes (Tpr A-L), two highly repetitive genes (arp, TPANIC 0470), and five FadL homologs 554 (TPANIC\_0548, TPANIC\_0856, TPANIC\_0858, TPANIC\_0859, TPANIC\_0865) using bedtools<sup>39</sup> 555 556 v2.29 maskfasta (positions listed in Supplementary Data 2). We mapped prefiltered sequencing reads to the reference using BWA mem<sup>40</sup> v0.7.17 (MapQ  $\geq$  20, excluding reads 557 558 with secondary mappings) followed by indel realignment using GATK v3.7 IndelRealigner, 559 deduplication with Picard MarkDuplicates v1.126 (available at 560 http://broadinstitute.github.io/picard/), and variant calling and consensus pseudosequence generation using samtools<sup>41</sup> v1.6 and bcftools v1.6, requiring a minimum of two supporting 561 562 reads per strand and five in total to call a variant, and a variant frequency/mapping quality 563 cut-off of 0.8. Sites not meeting our filtering criteria were masked to 'N' in the final 564 pseudosequence. After mapping and pseudosequence generation, we repeated the masking 565 of the 19 genes on the final multiple sequence alignment using remove block from aln.py 566 available at https://github.com/sanger-pathogens/remove blocks from aln/ to ensure

sites originally masked in the reference were not inadvertently called with SNPs due to mapped reads overlapping the masked region. These 19 regions of recombination and genomic uncertainty due to gene orthology or repetitive regions<sup>3,4,6</sup> accounted for 30,071 genomic sites (Supplementary Data 2).

571

572 For basic lineage assignment of genomes, we excluded sequences with >75% genomic sites 573 masked to 'N'. A SNP-only alignment was generated using snp-sites<sup>42</sup>, and a maximum 574 likelihood phylogeny was calculated on the variable sites using IQ-Tree<sup>27</sup> v1.6.10, inputting 575 missing constant sites using the `-fconst` argument, and using a general time reversible 576 (GTR) substitution model with a FreeRate model of heterogeneity<sup>43</sup> and 1000 UltraFast 577 Bootstraps<sup>44</sup>.

578

579 For finescale analysis of high-quality genomes, we excluded sequences with >25% genomic 580 sites masked to 'N' (i.e. >75% genomic sites passing filters at >5x and not masked). We used Gubbins<sup>26</sup> v2.4.1 (20 iterations) to generate recombination-masked full genome length and 581 SNP-only alignments. Gubbins<sup>26</sup> identified 19 further putative regions of recombination 582 583 affecting 2.1% of genomic sites (n=23,567) and 27 genes (listed in Supplementary Data 2), 584 meaning we masked a maximum of 4.7% (53,638 sites) of the genome over the 38 regions. 585 We used IQ-Tree on the SNP-only alignment containing 901 variable sites, inputting missing constant sites using the `-fconst` argument, and allowing the built-in model test to infer a 586 587 K3Pu+F+I model and 10,000 UltraFast bootstraps.

588

To cluster genomes, we initially performed joint ancestral reconstruction<sup>45</sup> of SNPs on the phylogeny using pyjar (available at <u>https://github.com/simonrharris/pyjar</u>), and used this to determine phylogenetic clusters with a 10 SNP threshold in rPinecone<sup>28</sup> (available at <u>https://github.com/alexwailan/rpinecone</u>). We further investigated this by using IQ-tree to generate 100 standard non-parametric bootstraps on the maximum likelihood phylogeny, and used the resulting 100 trees as independent inputs to rPinecone, as described in the rPinecone manuscript<sup>28</sup>. We used the hierarchical clustering 'hclust' algorithm in R<sup>46</sup> to group rPinecone clusters, and evaluated different proportions of trees supporting clustersagainst the phylogeny (Supplementary Figure 3).

598

599 For temporal analysis, our dataset was too large for robust model testing of all genomes, so we stratified our dataset by sublineage and country, then used the random sampler in R<sup>46</sup> to 600 select a maximum of five genomes from each strata, plus all singleton strains, yielding a 601 602 dataset of 138. We extracted the sequences from the multiple sequence alignment using seqtk and the subtree from our broader phylogeny using ape<sup>47</sup> v 5.4.1 `keep.tip`. Root-to-tip 603 distance analysis from this subtree showed a correlation of 0.327 and  $R^2$  of 0.11 604 (Supplementary Figure 15), and we proceeded to BEAST analysis. We initially ran BEAST<sup>30,48</sup> 605 606 v1.8.4 on our recombination-masked SNP-only alignment containing 592 variable sites, 607 correcting for invariant sites using the constantPatterns argument, in triplicate using both a Strict Clock model<sup>49</sup> (starting rate prior 1.78E<sup>-7</sup>) and an Uncorrelated Relaxed Clock model<sup>50</sup>, 608 with HKY substitution model<sup>51</sup> and diffuse gamma distribution prior<sup>52</sup> (shape 0.001, scale 609 610 1000) over 100 million MCMC cycles with 10 million cycle burnin. We evaluated constant, 611 relaxed lognormal, exponential and Bayesian Skyline (10 categories) population distributions<sup>53</sup>. All MCMC chains converged with high effective sample sizes, and on 612 613 inspection of the marginal distribution of ucld.stdev we could not reject a Strick Clock. We 614 used the marginal likelihood estimates from the triplicate BEAST runs as input to Path Sampling and Stepping Stone Sampling analysis<sup>54,55</sup>, and this suggested that the Strict Clock 615 616 with Bayesian Skyline was the optimal model for this dataset (Supplementary Figure 16), with an inferred molecular clock rate of  $1.23 \times 10^{-7}$  substitutions/site/year. To ensure that 617 618 our findings were not artefactual to the down-sampled dataset, we re-stratified the dataset 619 by sublineage, country and year, selecting a maximum of 3 genomes from each stratum, 620 plus all singleton strains, yielding a dataset of 168 genomes with 466 variable sites. We ran 621 BEAST on this new subsampled dataset using the optimal Strict Clock (with starting rate prior of 1.23 x10<sup>-7</sup>, inferred from the previous analysis) with Bayesian Skyline from above, 622 623 with the equivalent results (Supplementary Figure 17).

624

To evaluate the temporal dynamics of sublineages, we tested the temporal signal for the 4 largest sublineages 1, 2, 8, and 14 (Supplementary Figure 10). Sublineage 14 had poor temporal signal and was excluded from further analysis. We performed independent BEAST
analyses on the remaining sublineage multiple sequence alignments using the optimal Strict
Clock model with Bayesian Skyline (10 population groups), evaluating 3 independent chains
of 200 million cycles for each.

631

632 To analyse the full dataset (n=520 after excluding heavily passaged samples or those with 633 uncertain collection dates, 883 variable sites), after evaluating temporal signal 634 (Supplementary Figure 18), we initially attempted to reproduce our model in BEAST 1.8.4, 635 but this proved unachievable with our local implementation and compute arrangements. To 636 analyse the full dataset, we therefore reconstructed the optimal BEAST v1.8.4 model (Strict Clock with reference rate prior of 1.23  $\times 10^{-7}$ s/s/y, Coalescent Bayesian Skyline distribution 637 with 10  $populations^{51,53}$ ) in a BEAST2<sup>56</sup> v2.6.3 implementation with BEAGLE<sup>48</sup> libraries 638 639 optimised for Graphical Processing Units, analysing the 520 genomes over 500 million 640 MCMC cycles in triplicate.

641

To further confirm the temporal signal in our full 520 genome tree, we used the TIPDATINGBEAST<sup>57</sup> package in R to perform a date randomisation test, generating 20 new datasets with randomly reassigned dates – BEAST2 analysis using the same prior conditions found no evidence of temporal signal in these replicates, indicating that the signal in our tree was not found by chance (Supplementary Figure 19).

647

648 We used logcombiner to generate consensus log and treefiles, and treeannotator to create 649 median maximum credibility trees. We generated Bayesian Skyline and Lineage accumulation plots using the combined log and tree files in Tracer v1.7.1<sup>30</sup>, exporting the 650 651 data for subsequent plotting in R. To evaluate the posterior distribution of population 652 expansion times, we used the script population increase distribution BEAST.py (available 653 at https://github.com/chrisruis/tree scripts), which uses the BEAST log and tree files to 654 identify the first increase in relative genetic diversity from the PopSizes columns and the 655 date of this increase using the corresponding number of nodes in the GroupSizes columns 656 and the node heights in the respective tree. We required a 2-fold population expansion 657 (defined by setting `-p` to 100). The script outputs the proportion of trees in the posterior 658 distribution that support an increase in relative genetic diversity, along with the distribution of expansion dates, which we plotted in  $R^{46}$ . We repeated this analysis using the script 659 660 population change support\_BEAST.py (available at 661 https://github.com/chrisruis/tree scripts), which looks for an increase or decrease of 662 effective population size within a defined window, testing for supported start dates of a 2-663 fold population decline or expansion between 1990 and 2015.

664

665 Macrolide resistance alleles were inferred using the competitive mapping approach previously described<sup>4,36</sup> (available at https://github.com/matbeale/Lihir Treponema 2020). 666 667 To infer pairwise SNP distances between samples, we used pairsnp (available at 668 https://github.com/gtonkinhill/pairsnp). We constructed networks of minimum pairwise distance and shared lineages in  $R^{46}$ , and plotted these as heatmaps using ggplot2<sup>58</sup>. 669 Nucleotide diversity ( $\pi$ ) for different clades was inferred from the multiple sequence 670 671 alignments using EggLib<sup>59</sup> v3.0.0b21, including variable sites present in at least 5% of genomes. For geospatial analysis, we used the CoordinateCleaner<sup>60</sup> v2.0-17 package in R to 672 673 define the centroid position for each country, apart for Russia (where we used the centroid 674 of the Tuva Republic) and Mexico (where we used Mexico City). Geographic distances 675 between countries (using the country centroid or location defined above) were determined using the distVincentyEllipsoid function from the geosphere<sup>61</sup> v1.5-10 package. Correlations 676 677 between pairwise genetic, geographic and temporal distance were inferred using Pearson's 678 R Correlation via the 'cor' function in R, where we compared 'real' correlation with 1000 679 bootstraps resampled with replacement to obtain a p value. Sample counts were plotted using ggmaps<sup>62</sup> over maptiles downloaded from Stamen Design (http://maps.stamen.com). 680 All phylogenetic trees were plotted in R using ggtree<sup>63</sup>. All figures used ggplot2<sup>58</sup> v3.3.2 for 681 682 plotting.

683

## 684 Data Availability

Sequencing reads for all novel genomes have been deposited at the European Nucleotide
Archive in BioProjects PRJEB28546, PRJEB33181 and PRJNA701499. All accessions,

687 corresponding sample identifiers and related metadata are available in Supplementary Data688 1.

## 689 Acknowledgements

690 The authors acknowledge the sequencing team at the Wellcome Sanger Institute, and 691 Christoph Puethe and the Pathogen Informatics team for computational support. We thank 692 additional technical staff involved in sample diagnostics, DNA extraction and sample 693 retrieval in laboratories at Public Health England and NHS laboratories, UK; British Colombia 694 CDC and Alberta Precision Laboratories, Canada; National Public Health Center, Budapest, 695 Hungary; FRC Kazan Scientific Center, Tuva, Russia; National Institute for Communicable 696 Diseases, Johannesburg, South Africa; Institute of Tropical Medicine, Antwerp, Belgium; 697 Sahlgrenska University Hospital, Gothenburg, Sweden; Hospital Vall d'Hebron, Barcelona, 698 Spain; Midlands Regional Hospital Portlaoise, Ireland; Pathology Queensland Central 699 Laboratory, Australia; WHO Collaborating Centre for Gonorrhoea and other STIs, Sweden. 700 We thank G. Tonkin-Hill, A. van Tonder, and members of the Thomson team for helpful 701 discussions during analysis. MAB and NRT are supported by Wellcome funding to the Sanger 702 Institute (#206194). 867

# 868 Supplementary Figures

869 Supplementary Figure 1. Phylogenetic distribution of 726 Treponema pallidum ssp 870 pallidum partial genomes. Maximum likelihood phylogeny of 726 partial (>25% of genome 871 positions) genomes shows two primary lineages (Nichols, SS14), with no obvious correlation 872 by country or continent. Tree tip points are coloured by continent, while coloured strips 873 show continent, country and TPA lineage. One very low coverage sample (TPA BCC144, 874 Canada, 47% genome breadth, 7.9X mean coverage) appears basal to the SS14-lineage clade 875 in this phylogeny, but due to low coverage it was not possible to determine the correct 876 placement.

877

Supplementary Figure 2. Finescale analysis of 528 high quality (>75% reference sites) TPA
genomes and sublineages. Recombination masked WGS phylogeny of 528 genomes. Tree
tips and coloured strips show sublineage.

881

882 Supplementary Figure 3. Evaluating phylogenomic clustering using bootstrap resampled 883 trees. We generated 100 bootstraps from our finescale analysis of 528 TPA genomes, 884 independently running rPinecone (10 SNP threshold) on each bootstrapped tree. 885 Hierarchical clustering was used to group rPinecone sublineages, and we applied different 886 support thresholds (minimum % of trees remaining) to explore the consistency of 887 sublineages. Nichols-sublineages were all well supported, but some SS14-sublineages lacked 888 support in many bootstraps. To focus on the more stable sublineages we required that at 889 least 5% of the bootstrap replicates supported a cluster. Plot shows maximum likelihood 890 phylogeny, with metadata columns showing cluster assignment along the x-axis for the 891 original maximum likelihood cluster assignment, then allowing for 95%, 80%, 50%, 20% and

5% of bootstrap variation observed. Final sub-lineage assignments are shown against the 5% cluster assignments. Note that non-zero branch lengths were added by IQ-Tree during maximum likelihood tree estimation, leading to an artifactual ladder-like appearance for sublineage 1.

896

Supplementary Figure 4. Detailed subtree of SS14-lineage. Recombination masked WGS phylogeny, showing the SS14-lineage and sublineages. The low diversity globally distributed sublineage 1 has been collapsed to enable visualization of the remaining sublineages. Tip points are coloured by sublineage, and coloured strips show sublineage and country. Blue triangle indicates collapsed Nichols-lineage, pink triangle indicates collapsed sublineage 1. Two samples close to the root of the common SS14-lineage clades were clustered as sublineage 1, and are shown.

904

905 Supplementary Figure 5. Subtree highlighting novel Nichols-lineage strains. Recombination 906 masked WGS phylogeny, showing the Nichols-lineage and sublineages. Tip points are 907 coloured by sublineage, and coloured strips show sublineage and country. Shaded boxes 908 highlight basal Nichols-lineage outgroup sublineages 6 and 7. The large clonal sublineage 14 909 has been collapsed to enable clearer visualization of the remaining taxa. The pink triangle 910 indicates collapsed SS14-lineage, blue triangle indicates the collapsed sublineage 14.

911

912 Supplementary Figure 6. Commonly used Nichols Reference genomes form a 913 monophyletic clade unrelated to contemporary clinical strains. A- Recombination masked 914 WGS phylogeny, showing the Nichols-lineage and sublineages. Shaded grey box shows a 915 monophyletic clade containing commonly used reference genomes as well as genetically 916 related strains. Tip points are coloured by sublineage, and coloured strips show sublineage 917 and country. Pink triangle indicates collapsed SS14-lineage. B- Expanded view of a seemingly 918 extinct clade containing common reference strains including Nichols v2, DAL-1 and 919 Seattle Nichols. The most recent sample closely related to the reference strains (TPA USL-920 SEA-83-1) was collected in 1983, while the latest sample for the entire clade (TPA USL-Phil-921 3) was collected in 1987. The provenance of the sample originally used for sequencing the 922 DAL-1 genome is uncertain, but in the literature the original isolation was in 1988. The 923 placement of both DAL-1 and TPA\_USL-SEA-83-1 within the diversity of Nichols-1912 924 derivatives suggests the possibility of the samples being mislabeled in the handling 925 laboratories.

926

927 Supplementary Figure 7. Finescale analysis of 528 high quality TPA genomes and 928 sublineages, showing distribution of samples sequenced directly from clinical samples and 929 those passaged in rabbit model. A - Whole genome phylogeny showing distribution of 930 samples sequenced directly from clinical sample or rabbit-passaged. B - Distribution of 931 samples sequenced directly from clinical sample and rabbit-passaged samples according to 932 sublineage. Samples passaged in rabbits are distributed throughout the global TPA 933 phylogeny, and present in 9/17 sublineages. Older samples from before 2000 were isolated 934 via rabbit passage, and dominate extinct clusters, as well as clustering close to the most 935 recent common ancestor of contemporary sublineages such as SS14 sublineage 1.

936

937 Supplementary Figure 8. Bayesian Skyline analysis of population decline and expansion 938 start dates. Plots show posterior distribution of supporting trees for the start of either a 2-939 fold decline (pink) or expansion (blue) using a scanning approach within a window of 1990-940 2015. Analysis provides strong support for a population bottleneck in or around 2000, and 941 moderate support for a subsequent expansion after 2010. Population changes are scaled to 942 the population size averaged over the starting period for each tree. Therefore, if a particular 943 tree already exhibited a decline near the starting timepoint, this may mean this tree does 944 not show expansion, resulting in reduced overall support for expansion.

945

Supplementary Figure 9. Bayesian Skyline analysis of sublineages. Plots show population
expansions occurring during the early 2000s for all sublineages with >15 samples apart from
sublineage 14. Sublineage 14, which had low temporal signal, did not converge after
multiple BEAST runs. Shows Skyline plots of sublineages 1, 2, 8 and plot for all samples from
Figure 5.

951

952 Supplementary Figure 10. Subtrees of major sublineages, with corresponding root-to-tip 953 distance plots. All subtrees showed some evidence of temporal signal, but this was very 954 weak for the recently emerged sublineage 14. Graphs are annotated with slope and time to 955 most recent common ancestor (TMRCA) inferred directly from the maximum likelihood 956 subtree, not BEAST.

957

958 Supplementary Figure 11. Finescale analysis of 528 high quality TPA genomes and 959 sublineages, highlighting private and singleton sublineages. Private and singleton 960 sublineages are nested within the existing diversity of the TPA phylogeny. Tip points indicate 961 sublineage, coloured tracks highlight singletons or private sublineages (with corresponding 962 sublineage number), and country.

963

Supplementary Figure 12. Effect of geographic distance on genetic distance. A- Pairwise
comparison of genetic distance (SNPs) and geographic distance (km; calculated using
country centroids) within Nichols- and SS14-lineages, including linear regression (95% CI not
visible). B- Pairwise comparison of genetic distance (SNPs) and geographic distance (km;
calculated using country centroids) within the four major multi-country sublineages (SS14:
1, 2; Nichols: 8, 14). Includes linear regression (95% CI not visible)

970

971 Supplementary Figure 13. Sharing of sublineages and closely related strains within and 972 between British Columbia (Canada) and England (UK). A- Syphilis incidence per 100,000 973 population by year for British Columbia, (Canada) and England (UK) using currently 974 published data. B- TPA sublineage counts for each year, using high quality genomes from 975 British Columbia (n=84) and England (n=240). British Columbia samples collected from 2000-976 2018, English samples collected from 2012-2018. C- Pairwise comparison of SNP distance 977 distributions from samples within and between British Columbia and England. D-978 Comparison of SNP distance and temporal distance within and between British Columbia 979 and England. The plot is divided into hexagonal bins, with the colour of each hexagon 980 representing the number of comparisons (white=none, purple=few, green=many, see scale). 981 Linear regression lines also shown (95% CI not visible).

Supplementary Figure 14. Multicountry sublineages are broadly macrolide resistant. A-Whole genome phylogeny showing distribution of macrolide resistance conferring SNPs (A2058G and A2059G). B- Distribution of macrolide resistance SNPs by sublineage, indicating number of samples per sublineage, and sublineage type. Note that while the common A2058G mutation was found in six sublineages (both Nichols- and SS14-lineages), we also found the less common A2059G in both SS14-lineage (sublineages 1, 2) and Nicholslineage (sublineage 6).

990

991 Supplementary Figure 15. Maximum Likelihood phylogeny of 138 representatively 992 subsampled genomes. A- Maximum likelihood phylogeny of 138 genomes randomly 993 sampled to be representative of sublineage and country. B- Scatterplot showing root-to-tip 994 distance against collection date, illustrating temporal signal in the dataset. C- Expanded 995 version of B, showing regressed x-intercept.

996

997 Supplementary Figure 16. Bayesian maximum credibility phylogeny of 138 representative 998 genomes shows population contraction during the 1990s, followed by rapid expansion 999 from the early 2000s onwards. A- Time-scaled phylogeny of 138 genomes randomly 1000 sampled to be representative of sublineage, country and collection year. Coloured tracks 1001 indicate sublineage, country and collection year. Node points are shaded according to 1002 posterior support (black ≥96%, dark grey >91%, light grey >80%). Red bars on nodes indicate 1003 95% Highest Posterior Density intervals. Blue line and shaded area highlights post-2000 1004 expansion of lineages. B- Bayesian Skyline plot shows decline of effective population size 1005 after the second world war, flattening in the 1960s, followed by a sharp decline and rapid 1006 reemergence during the 1990s and 2000s.

1007

Supplementary Figure 17. Secondary BEAST analysis of 168 separately subsampled representative genomes. A- Time-scaled phylogeny of 168 genomes randomly sampled to be representative of sublineage, country and collection year. Node points are shaded according to posterior support (black ≥96%, dark grey >91%, light grey >80%). Red bars on

982

nodes indicate 95% Highest Posterior Density intervals. Blue line and shaded area highlights
post-2000 expansion of lineages. B- Bayesian Skyline plot shows decline of effective
population size after the second world war, flattening in the 1960s, followed by a sharp
decline and reemergence during the 1990s and 2000s, indicative of a sharp bottleneck.

1016

1017 Supplementary Figure 18. Maximum likelihood tree of 520 TPA genomes with minimal 1018 passage and robust collection dates, with corresponding root-to-tip distance plot. Within 1019 the full tree, the temporal signal was weaker than in our subsampled dataset, but still 1020 plausible, given our prior analyses. Graphs are annotated with slope and time to most 1021 recent common ancestor (TMRCA) inferred directly from the maximum likelihood subtree, 1022 not BEAST.

1023

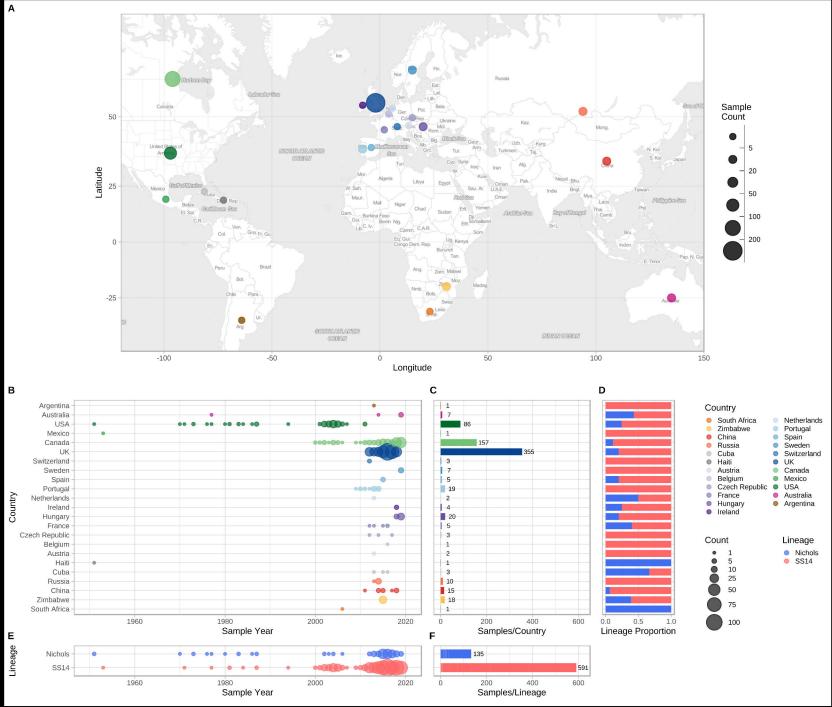

1024 Supplementary Figure 19. Date Randomisation Test for full BEAST2 dataset confirms the 1025 temporal signal in the true dataset compared to 20 resampled datasets with randomly 1026 reassigned tipdates. The median clock rate for the real dataset was  $1.27 \times 10^{-7}$ , while all 1027 randomly assigned datasets gave substantially lower clock rates; the highest median clock 1028 rate for the randomized datasets was  $8.02 \times 10^{-9}$ . Real sample (blue), randomized samples 1029 (pink).

1030

**Supplementary Data 1.** Metadata and read accessions for all samples included in this study

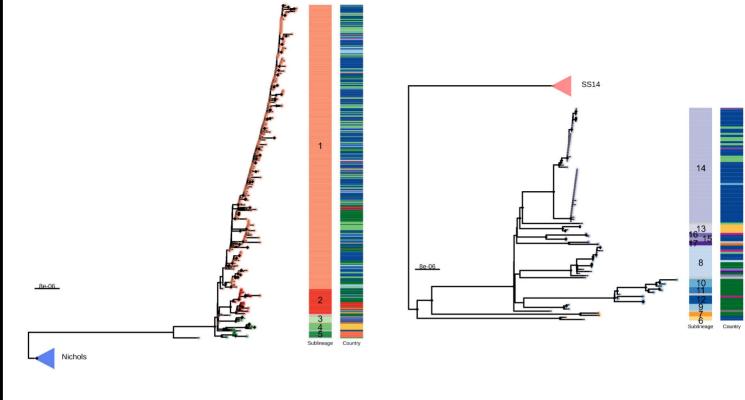

1032

1033 Supplementary Data 2. Genomic regions masked due through prefiltering or recombination1034 analysis.
