24 **Abstract**

25 **Background and Objective**

26 Coronavirus disease 2019 (COVID-19) manifests as multiple clinical and pathological organ
27 dysfunctions. It also disrupts metabolic profile due to the release of pro-inflammatory cytokines
28 causing a systemic inflammation reaction. However, the development and correlation of
29 dyslipidemia with acute phase reactants is unknown. This investigation was performed to assess
30 the pathological alterations of low-density lipoprotein cholesterol (LDL-C), high-density
31 lipoprotein (HDL), triglycerides, and total cholesterol levels in COVID-19 patients.

32 **Methods**

33 This was a prospective study performed on real-world patients to assess serum levels of LDL-C,
34 HDL, TG, TC on COVID-19 patients (mild: 319; moderate: 391; critical: 357) hospitalized at
35 our center between April 2020 through January 2021. Age- and gender-matched controls who
36 had their lipid profiles in the same period were included as the control group.

37 **Results**

38 LDL-C, HDL, TG, and TC levels were significantly lower in COVID-19 patients when
39 compared with the control group ($P < 0.001$, 0.047, 0.045, < 0.001 , respectively). All parameters
40 decreased gradually with COVID-19 disease severity (LDL-C: median (IQR), mild: 98 (91,134);
41 moderate: 97 (81,113); critical: 68 (68,83); HDL: mild: 45 (37,50); moderate: 46 (41,50);
42 critical: 40 (37,46); TG: mild: 186 (150,245); moderate: 156 (109,198); critical: 111 (98,154);
43 TC: mild: 224 (212,238); moderate: 212 (203,213); critical: 154 (125,187)). LDL-C, TC, and TG
44 were inversely correlated with acute phase reactants (interleukin-6 (IL-6), Procalcitonin, C-

45 reactive protein (CRP), and D-dimers). Logistic regression demonstrated lipid profile, thyroid
46 profile, and acute phase reactants as predictors of severity of COVID-19 disease.

47 **Conclusion**

48 Hypolipidemia develops in increasing frequency with severe COVID-19 disease. It inversely
49 correlates with levels of acute-phase reactants, indicating SARS-COV-2 as the causative agent
50 for alteration in lipid and thyroid levels.

51 **Keywords:** COVID-19, Hypolipidemia, LDL-C, HDL, total cholesterol

52 **Introduction**

53 Coronaviruses include a large family of viruses notorious for causing a multitude of diseases in
54 humans, ranging from common flu to more serious conditions like Middle Eastern Respiratory
55 Syndrome (MERS) or Severe Acute Respiratory Syndrome (SARS) [1]. The causative agent for
56 coronavirus disease 2019 (COVID-19) is the SARS coronavirus 2 (SARS-COV-2) that causes
57 various manifestations of the disease, involving the respiratory, gastrointestinal, hematological,
58 endocrine, and cardiovascular systems [2,3]. Even after the mitigation measure, the estimated
59 basic reproduction (R_0) ranges from 2.24 to 3.58 and the mortality rate of COVID-19 is
60 considered to be 2.3% [4,5,6]. World Health Organization (WHO) declared COVID-19 as a
61 pandemic and initiated a global emergency from 11th March 2020 [7].

62 SARS-COV-2 is a positive-stranded RNA virus with an envelope of lipid bilayer, and a genome
63 of approximately 30,000 nucleotides. On an electron microscope four major proteins have been
64 identified as an integral part of the virus: the nucleocapsids (N) protein, the crown or spike (S)
65 protein, the membrane (M) protein, and the envelope (E) protein [8]. These proteins play an
66 important role in human infectivity and among them, the S protein mediates attachment to

67 human hosts via angiotensin-converting enzyme 2 (ACE2) receptors [9]. An expression of ACE
68 2, in combination with transmembrane protease serine 2 (TMPRESS2), seems to be the key
69 cellular mechanism for human infection [10].

70 In SARS-COV-2, lipids are an essential component for maintaining the integrity of the viral
71 membrane and its fusion to the host cells, viral replication, endo/exocytosis, and human host
72 infiltration. Some preliminary reports have described lipid abnormalities associated with the
73 severity of disease in COVID-19 [11,12]. Therefore, this investigation was aimed to assess the
74 lipid profile and its correlation with other biochemical tests used to predict the severity of
75 COVID-19.

76 **Methods**

77 **Study design and patient demographics**

78 This prospective study was carried out at Infectious Disease Block, Advanced Diagnostics and
79 Liver Center, Rawalpindi, and was approved by the Review Committee (Study ID#ADC/20/006)
80 of Advanced Diagnostics and Liver Center according to the ethical principles of the Declaration
81 of Helsinki. Written, informed consent was taken from all the participants/guardians before data
82 collection. A total of 1,755 patients were enrolled in this investigation: 1067 with COVID-19 and
83 688 healthy adults as controls from April 2020 through January 2021. All the data regarding
84 demographics, epidemiology, comorbidities, laboratory tests, and hospital stay were extracted
85 electronically. SARS-COV-2 positive patients were confirmed using real-time reverse
86 transcription-polymerase chain reaction (RT-PCR). Pneumonia was classified according to the
87 guidelines issued by the Centers for Disease Control (CDC) as labeled as mild, moderate, or
88 severe on high resolution computed tomography (HRCT) scans according to our previous study

89 [13]. HRCT was considered positive if it demonstrated consolidation, septal thickening, linear
90 opacities, crazy-paving pattern, or halo sign. Mild disease was classified as less than 10% lung
91 involvement with normal room oxygen saturation. Moderate cases were classified as less than
92 50% lung involvement on HRCT with respiratory rate of >30 breaths/min, and oxygen saturation
93 of < 90% at rest requiring <10 ml/min of oxygen. Those requiring >10 ml/min of oxygen and/or
94 ventilatory support were labeled as critical cases. Age- and gender-matched healthy adults, who
95 had their lipid profile panel done at our clinic were included as controls. Their data were not
96 identified and only age, gender, BMI, and lipid profile were extracted.

97 **Laboratory tests**

98 All the laboratory tests were carried out at our certified laboratory in Advance Diagnostics under
99 the standard procedures of the Punjab Healthcare Commission. Hemoglobin (Hgb), and white
100 blood cells (WBC) were performed on a Sysmex automated hematology analyzer (XN-3100™).
101 Alanine aminotransferase (ALT), aspartate aminotransferase (AST), low-density lipoprotein
102 cholesterol (LDL-C), high-density lipoprotein (HDL), total cholesterol (TC), and triglycerides
103 (TG) were tested on Cobas® c3011 analyzer (Roche Diagnostics). Free triiodothyronine (T3),
104 free thyroxine (T4), thyroid-stimulating hormone (TSH), interleukin-6 (IL-6), and Procalcitonin
105 were analyzed via electrochemiluminescent immunoassay (ECLIA) in the Elecsys® 2010
106 immunoassay system. All parameters were compared between the COVID-19 classification. In
107 addition, the lipid profile was compared between the control group and COVID-19. All tests
108 were drawn in a fasting state from the blood samples on admission.

109 **Statistical analysis**

110 Data were analyzed with Statistical Package for the Social Sciences (SPSS) version 26 (IBM
111 Corp, Armonk, NY, USA.). Normally distributed continuous variables were presented as mean \pm

112 standard deviation (SD) while Non-normally distributed variables as median (interquartile
113 range). Categorical variables were presented in frequency and percentages. Normality test
114 adjustment was applied through the Shapiro-Wilk test. The groups were compared using
115 Student's t-test (normal distribution) and the Mann-Whitney U test (non-normal distribution).
116 Chi-square was used to compare categorical variables and the Kruskal-Wallis test was used to
117 compare variables among multiple groups. A receiver operating characteristic (ROC) curve was
118 calculated for all laboratory parameters to demonstrate sensitivity and specificity in the COVID-
119 19 cohort. Odds ratio (OR) and confidence interval (CI) were presented for all tests performed.
120 Scatter plots were demonstrated using Pearson correlation analysis. A p-value of less than 0.05
121 was considered significant.

122 **Results**

123 A total of 1067 COVID-19 patients were included in this investigation: 319 were mild, 391
124 moderate, and 357 as critical cases. The ages for the COVID-19 cohort was approximately
125 similar: mild (47.83 ± 19.66 years), moderate (47.87 ± 19.21 years), and critical (47.29 ± 18.76
126 years) while the mean age for age- and gender-matched control subjects was 57.37 ± 4.62 years.
127 The patients in this group were significantly older than the COVID-19 cohort. Both COVID-19
128 and control groups had a majority of the male population (66.7% and 68.4%,
129 respectively). **Table 1** demonstrates patient demographics and lab parameters in the control as
130 well as COVID-19 groups. Forty-seven patients did not survive with a mortality rate of 4.4%.
131 Biochemistry and hematology results showed that Hgb was significantly more in mild cases
132 while WBC was increased in moderate and critical cases. AST, ALT, creatinine, CRP, D-dimers
133 were all significantly increased in higher COVID-19 class while free T3, free T4, and TSH were
134 markedly reduced in critical cases (**Table 1**). LDL-C, HDL, TC, and TG levels were

135 significantly lower in COVID-19 patients as compared to control subjects. All lipid profiles
136 decreased gradually and significantly in critical cases as compared with mild and moderate
137 cases. **Figure 1** and **Table 2** demonstrate the receiver operating characteristic (ROC) curve
138 exhibiting the sensitivity and specificity of the lab parameters in predicting the progression of
139 COVID-19 disease. Correlation of LDL-C, HDL, TC, and TG with acute phase reactants is
140 shown in **Figure 2**.

141 Logistic regression analysis was performed to determine predictors of severe COVID-19 disease
142 among all subjects. The model suggested LDL-C, HDL, TC, TG, free T3, free T4, TSH, IL-6,
143 Procalcitonin, CRP, and D-dimers as independent risk factors for COVID-19 (**Table 3**).

144 **Discussion**

145 Key findings of this investigation were as follows: Levels of LDL-C, HDL, TC, and TG all
146 decreased significantly with increasing severity of COVID-19 while acute phase reactants like
147 IL-6, Procalcitonin, CRP, and D-dimers were increased in this cohort and thyroid function tests,
148 lipid profile parameters, and acute phase reactants were predictors of severe disease of COVID-
149 19. This is the first prospective report with lipid profile data of real-world patients suffering from
150 COVID-19 and this investigation points out that lipid levels start decreasing even in mild cases
151 while reduced lipid levels inversely correlate with acute phase reactants. Also, it provides
152 evidence of altered biochemistry and pathological evolution of lipidology in COVID-19.

153 Viral infections cause alterations of lipid biomarkers in their hosts, leading to disrupted
154 cholesterol rafts. This helps them in infiltrating the host defenses. In response to acute
155 inflammatory conditions in COVID-19, termed as cytokine storm, there is dysfunction of HDL
156 and LDL-C particles. In addition, a surge of pro-inflammatory cytokines can cause a
157 consumption of albumin, ApoA1, HDL, TC, TG, LDL-C, along with decreased lymphocytes

158 [14]. Therefore, according to our study, the depressed lipid parameters can be a predictor for the
159 severity of COVID-19 disease [11]. Similarly, a study in China described the lipid profile and
160 other clinical characteristics of COVID-19 [15]. The levels of LDL-C, HDL, and TC were
161 significantly decreased in their patients, and this alteration was gender-specific. In contrast to our
162 study, males more commonly presented with lowered lipid levels in their investigation. A
163 significant decrease in HDL was seen only in critical cases of COVID-19 while a significant
164 decrease of LDL-C, TC, and TG was observed in all COVID-19 groups (mild, severe, critical).
165 However, in our study HDL, LDL-C, TG, and TC were significantly depressed only in the
166 critical COVID-19 cohort. In contrast to these investigations, a preprint reports significantly
167 increased levels of LDL-C compared to control groups and a positive relationship of COVID-19
168 severity with elevated lipid profile alterations [16].

169 Similar findings have been demonstrated in human immunodeficiency virus (HIV), where
170 acquired immunodeficiency syndrome (AIDS) patients exhibit an elevated level of plasma
171 triglycerides and decreased HDL and LDL-C [17]. Furthermore, HIV-infected individuals have
172 the propensity to develop various other lipid abnormalities like hypocholesterolemia and
173 decreased free fatty acids [18]. A study analyzed lipid metabolism in SARS-recovered patients at
174 12 years' interval and demonstrated hypertriglyceridemia and an elevated very-low-density
175 lipoprotein (VLDL) cholesterol [19].

176 These findings can be explained by the composition of HDL, which contains esterified
177 cholesterol, Apo-lipoproteins, and triglycerides. These lipid fragments impart an important role
178 in small-vessel vasodilation, and in the reduction of oxidation and free radical formation,
179 apoptosis, thrombosis, infection, and inflammation [20]. In addition to its contribution as an anti-
180 inflammatory lipoprotein, HDL downregulates inflammatory mediators by inactivating T-cells

181 and macrophages [21]. In COVID-19, a surge in pro-inflammatory cytokines confer the presence
182 of systemic inflammation. HDL can deactivate this inflammatory cascade by inhibiting the
183 activation of monocytes and neutrophils while maintaining an antioxidant function, allowing for
184 the removal of oxidized lipids and neutralizing oxidative factors. This in turn mitigates
185 inflammatory response in the host cells [22]. During a cytokine storm in COVID-19, HDL and
186 LDL-C are oxidized, leading to an upregulation of immune activation [23,24]. Based on the
187 immunomodulatory mechanism of HDL, we can consider immune regulation in COVID-19 as
188 the primary cause for decreased lipid levels in this investigation.

189 There were several limitations of this investigation. First, the time of symptom onset to the time
190 of sample collection was variable in this cohort. Therefore, the analysis might represent
191 heterogeneous results of the COVID-19 disease course. Second, many patients were already on
192 statin treatment and the level of precise alteration in lipid profile during the disease course of the
193 COVID-19 cohort could be biased towards depressed lipid levels in these patients. Third, the
194 control group patients were healthy individuals with no severe or critical form of acute illness.
195 This could have produced a sample selection bias, producing abnormal results in this
196 investigation. Fourth, no follow-up data of the lipid profile and its alteration was collected for
197 monitoring the dynamics of COVID-19. This will be needed for better characterization of this
198 phenomenon in the COVID-19 cohort.

199 **Conclusion**

200 The ongoing COVID-19 outbreak caused by SARS-COV-2 poses a great challenge to the human
201 population with a pressing need to understand viral mechanisms and develop effective antiviral
202 agents. As cholesterol is involved in many vital cellular processes in regulating the viral entry
203 into the host cell, the results of this investigation demonstrate a correlation of the severity of

204 COVID-19 disease with altered lipid profile parameters. Decreased levels of LDL-C, HDL, TC,
205 and TG validate the mechanism of immune upregulation by HDL and its byproducts, causing a
206 negative correlation between lipids and acute phase reactants released as pro-inflammatory
207 cytokines in COVID-19.
