Abstract

Objective: We aimed to develop an early warning system for real-time sepsis prediction in the ICU by equipping with interpretation analysis and transfer learning tools to improve the feasibility to deploy the sepsis prediction system, particularly to target cohorts.

Design: Retrospective and observational study.

Setting: Medical Information Mart for Intensive Care (MIMIC) dataset, the private Historical Database of local Ruijin Hospital (HDRJH), and data collected from Ruijin real-world study.

Patients: 6891 patients from MIMIC dataset and 453 patients from HDRJH for model development and 67 cases from Ruijin real-world data for model evaluation.

Interventions: None.

Measurements and Main Results: Light Gradient Boosting Machine (LightGBM) and multilayer perceptron (MLP) were trained on MIMIC dataset and then finetuned on HDRJH using transfer learning technique. Ultimately, the performance of the sepsis prediction system was further evaluated in the real-world study in the ICU of the target Ruijin Hospital. The area under the receiver operating characteristic curves (AUCs) for LightGBM and MLP models derived from MIMIC were 0.98–0.98 and 0.95–0.96 respectively on MIMIC dataset, and, in comparison, 0.82–0.86 and 0.84–0.87 respectively on HDRJH, from 1–5h preceding. After transfer learning and ensemble learning, the AUCs of the final ensemble model were enhanced to 0.94–0.94 on HDRJH and to 0.86–0.9 in the real-world study in the ICU of the target Ruijin Hospital. In addition, the Shapley additive explanation (SHAP) analysis illustrated the importance of age, antibiotics, net balance, and ventilation for sepsis prediction, making the model interpretable.

Conclusions: Our machine learning model allows accurate real-time prediction of sepsis within 5-h preceding. Transfer learning can effectively improve the feasibility to deploy the prediction model in the target cohort, effectively ameliorating the model performance for external validation. SHAP analysis may illuminate the importance of optimizing antibiotic use and restricting fluid management.

Trial registration: NCT05088850 (retrospectively registered).

Keywords: Sepsis, Intensive care unit, Machine learning, Transfer learning, Prognostication, Model interpretability

Key Points

Question: We aimed to develop an early warning system for real-time sepsis prediction in the ICU and to improve the feasibility to deploy the system to target cohorts.

Findings: Transfer learning technique effectively enhanced the AUCs for LightGBM and MLP models on the target cohort, HDRJH, from 0.82–0.86 and 0.84–0.87 to 0.93-0.94 and 0.92-0.93 for 1-5 hour preceding. Additionally, SHAP analysis illuminated the importance of optimizing antibiotic use and restricting fluid management.

Meaning: Transfer learning can improve the feasibility to deploy the prediction model to the target cohort, and SHAP analysis made the prediction model interpretable.

Sepsis, an infection-induced syndrome of physiological, pathological, and biochemical abnormalities, is a global healthcare issue associated with unacceptably high mortality and long-term morbidity among patients in the intensive care unit (ICU) (1,2), and is responsible for a substantial cost burden on health care resources (3). Early detection and timely administration of appropriate antibiotics are important for improving the prognosis and survival of septic patients (4). However, nonspecific symptoms of sepsis may cause delayed diagnosis and intervention, leading to the high mortality of septic patients (5).

Machine learning has emerged as a promising tool for the early detection of sepsis occurrence based on electronic medical records, laboratory data, and biomedical signals (6-14). Several prospective studies have shown that implementation of machine learning-based sepsis prediction algorithms can reduce in-hospital mortality and length of stay (15,16). Except for the excellent prediction performance, the translation of these risk prediction models into clinical practice requires external independent validation to determine the generalizability of the model to different cohorts (17). However, most of the newly proposed risk prediction models have discriminatory performance when applied to external samples (18). Re-training of the prediction model on local datasets in the target medical center might enhance the predictive accuracy in the specific situation (19). Transfer learning as a re-training approach has been reported to improve model performance when the dataset is small in the target medical center (20,21). Additionally, the interpretability of machine learning models reflects the extent to which the decision-making process of the model can be understood and accepted in clinical practice. The lack of interpretability for most available prediction models is currently the major barrier to their clinical adoption (22,23). The objective of this study is to

develop an interpretable early warning system (named SEPRES, Sepsis PREdiction System) for real-time sepsis prediction in the ICU and to improve its generalizability to the target medical center through transfer learning technique.

Methods

SEPRES includes a data integration system equipped with a sepsis early warning module. The data integration system collects, stores, processes, and displays medical data. The sepsis early warning module included a sepsis prediction model and an interpretative tool. The sepsis prediction model is an ensemble of multiple machine learning models. The interpretative tool provides information on how the model works by assigning importance to the input features. Our study complies with the relevant reporting guidelines, namely the Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis (TRIPOD) statement (24). The study protocol complies with the Declaration of Helsinki, as revised in 2013, and was approved by the Ruijin Hospital Ethics Committee (No. 2020 [140], approved on October 27, 2020, study title: The early. Prediction of sepsis occurrence in ICU). Written informed consent was obtained from individual or guardian participants.

Data acquisition

Data sources

Our study used the Medical Information Mart for Intensive Care (MIMIC-III) database (version 1.4) (25) and the private Historical Database of Ruijin Hospital (HDRJH). MIMIC encompasses 61532 patients admitted to the ICU at Beth Israel Deaconess Medical Center in Boston from 2001 to 2012, and HDRJH encompasses approximately 1777 patients from 2011 to 2019. In addition to retrospective data, we also collected predictions of consecutive 67

patients from the SEPRES system running in the ICU at Ruijin (RJ) Hospital between February 2021 and June 2021 as a validation of the model in the real world.

Sepsis definitions

We defined sepsis according to the definition of the Third International Consensus for sepsis (Sepsis-3) (2), combining suspected infection and SOFA score.

Feature extraction

We extracted 78 and 63 patient variables from the MIMIC and HDRJH, respectively. After data cleaning, we extracted these variables as features, i.e., maximum, average, median, and minimum, at hourly intervals, and the missing data were padded by the nearest value before or a preset default value. We filtered out 1057 positive and 5834 negative patients in the MIMIC dataset, and 144 positive and 309 negative patients in the HDRJH dataset, respectively. We used a 5-h time window from the patients to predict sepsis.

See Appendix 1 for details.

Machine learning models

In the following two sections, we describe the methodology for developing a sepsis prediction model that outputs the risk of sepsis onset within 5-h preceding at most. To improve the prediction performance in the specific hospital and to avoid the poor performance of direct training due to its insufficient data, the models were first trained in MIMIC and then finetuned in HDRJH using transfer learning techniques. The ultimate sepsis prediction model was obtained by integrating multiple models using ensemble learning techniques.

Multiple models were trained on the MIMIC dataset, including support vector machine (SVM), multilayer perceptron (MLP), gradient boosting machine (GBM), and long short-term

memory (LSTM). For GBM, we used XGBoost (26) and LightGBM (27) as implementations. We utilized the standard training methods to train these models with necessary normalization which can be summarized by the following formula:

$$\tilde{x}_j^i = \frac{x_j^i - \min\limits_{i'} x_j^{i'}}{\max\limits_{i'} x_j^{i'} - \min\limits_{i'} x_j^{i'}}$$

where x_j^i is the value of the j-th feature of the i-th sample, and $\tilde{x}_j^i$ is the value after scalarization. The hyperparameters and structures of each model were tuned based on the validation set.

See Appendix 4 and 5 for details.

Transfer learning

Based on the integrated considerations of the performance including accuracy, the area under the receiver operating characteristic curve (AUC), sensitivity, and inference speed on the MIMIC dataset, we selected the LightGBM and MLP for sepsis prediction on the RJ Hospital data.

The process of transfer learning can be divided into two steps. First, we normalized the data in the MIMIC dataset and the HDRJH dataset respectively so that the features are all scaled between 0 and 1. Second, we performed the transfer of the model parameters. Specifically, for LightGBM, the previous four hours of features in MIMIC were masked during training to assist transfer learning. After that, the HDRJH dataset was fed to finetune with the initial parameter values taken from the trained model from MIMIC. For MLP, we first froze the parameters of the first three of the six layers of the MIMIC models and initialize the parameters of the last three layers. After training on HDRJH, the models were unfrozen and

fine-tuning is performed. We also used an ensemble learning method to integrate the LightGBM and MLP models by taking the inference average. The ensembled model is employed for practical sepsis prediction in RJ Hospital.

Interpretive analysis

We interpreted our prediction models using Shapley additive explanation (SHAP) (28), a game theory-based approach that assigns an importance value to each feature of each prediction.

Real-time prediction system

We detail the implementation of our real-time prediction system in (29). When a model inference command is executed, the sepsis early warning module obtains real-time features of the patient from the data integration system via SQL query statements, which are then preprocessed, inferred, and interpreted by the module. The data integration system includes a physical server with the PostgreSQL database for storage of sepsis warning related data and a webserver deploying the portal for user access. The medical device integration hub was placed at the bedside, receiving and transmitting data to the data integration system with a time delay of less than 10 s. Using the network or RS-232 interface, the data integration system can integrate data from IntelliVue Information Center, ventilators, Philips ICCA system, Laboratory Information System (LIS), and Hospital Information System (HIS).

Results

Characteristics of patients from different datasets

The baselines of characteristics of patients from MIMIC-III, HDRJH, and Ruijin real-world data were analyzed. As shown in Table S2, the baselines of most characteristics were

significantly different between patients from MIMIC-III and patients from HDRJH except for 21 characteristics. Therefore, to avoid the influence of these differences on model performance in the target cohort, retraining of the model was performed on HDRJH using transfer learning technique after training on MIMIC-III.

Prediction performance on internal and external validation of MIMIC-III

The performance of our sepsis prediction models has been evaluated based on the accuracy, AUC, sensitivity, and specificity on the test set. As shown in Figure S3, the GBM-based models (XGBoost and LightGBM) outperformed others (See Table S3 for the performance of the five models). Furthermore, we compared our LightGBM and MLP models with other proposed models developed from MIMIC-III using Sepsis-3 criteria and reported the prediction outcomes within 5 hours before the onset of sepsis. As shown in Table 1, our LightGBM and MLP models were superior to the others, with AUC of 0.98 and 0.96 respectively. However, it should be noticed that although these models all used MIMIC-III database, there were still differences in the training and test sets due to specific data extraction and sepsis criteria.

Model	Preceding hours	Accuracy	AUC[1]	Sensitivity	Specificity
InSight	4	0.57	0.74	0.8	0.54
AISE[2]	4	0.64	0.84	0.85	0.64
MGP-TCN[3]	4	-	approximately 0.85	-	-
DTW-KNN[4]	4	-	approximately 0.88	-	-
MLA[5]	0	-	0.88	0.8	0.78
MLA	24	-	0.84	0.8	0.72
DSPA[6]	4	-	0.98	-	-
MGP-AttTCN[7]	4	-	0.75	-	-
NAVOY Sepsis	3	0.81	0.84	0.74	0.83
LightGBM	4	0.91	0.98	0.85	0.97
MLP[8]	4	0.85	0.96	0.73	0.96

Table 1. The results of different models on the MIMIC-III dataset

For the external validation of our LightGBM and MLP models, we evaluated their prediction

performances on HDRJH, the dataset from the target medical center (the ICU in RJ Hospital).

The AUCs were 0.82−0.86 and 0.84−0.87 respectively on HDRJH from 1−5h preceding,

indicating the substantially worsened performance of these models when applied to external

independent cohorts.

Improved prediction performance on HDRJH after transfer learning

To improve the prediction performance on HDRJH, these models were retrained and

ensembled using transfer learning and ensemble learning technique. As shown in Table 2,

transfer learning improved the prediction performance when deploying the models derived

from the public dataset (MIMIC) to the target hospital (HDRJH). The ultimate AUCs of the

[7] Multi-task Gaussian Process and Attention Time Convolutional Network
[8] Multilayer Perceptron

ensemble sepsis prediction model were 0.94–0.94 from 1−5h preceding on HDRJH, as shown

in Table S4.

Model	Transfer learning	Training set	Accuracy	AUC
LightGBM	N	MIMIC	0.74	0.86
LightGBM	N	HDRJH	0.81	0.92
LightGBM	Y	MIMIC+HDRJH	0.83	0.93
MLP	N	MIMIC	0.76	0.86
MLP	N	HDRJH	0.84	0.92
MLP	Y	MIMIC+HDRJH	0.78	0.93

These models predict sepsis in 4-h preceding and the complete results can be found in Table S5 and S6. MIMIC+HDRJH means training on MIMIC first and then tuning on the training set of HDRJH by transfer learning techniques.

Table 2. The results of models trained on different datasets on the HDRJH test set

Furthermore, as shown in Figure 1, LightGBM and MLP models showed consistent transfer

benefits on the target hospital at different sampling ratios of the target hospital dataset.

Meanwhile, the models after transfer learning showed higher AUCs on MIMIC, indicating

improved generalizability of the model to different datasets.

Figure 1: The results of models trained on sampled HDRJH dataset. The training set of HDRJH was sampled at different ratios to simulate a medical center with fewer records. These trained models were tested on the common MIMIC test set (top) and the HDRJH test set (bottom), respectively. The shaded part in the figure represents the 95% confidence interval. These models predict sepsis in 4-h preceding and the complete results can be found in Figure S5-8.

Feature interpretability of the prediction models

The top 20 features for the LightGBM model predicting sepsis in 4-h preceding were shown

in Figure 2, and the results for full analysis of LightGBM and MLP models were shown in

Figure S10, 11. Some of these features (antibiotics, respiratory rate, temperature, ventilation,

and heart rate) were related to the definition of Sepsis-3 or SIRS. Additionally, the association

of some of these features (respiratory rate (30), fibrinogen (31), net balance (32), and age (33))

with the severity or mortality of sepsis has been reported. These data indicate the good

interpretability of our prediction model for clinical application.

Figure 2: Feature importance of LightGBM model in the sepsis early warning module.
The model predicted sepsis in 4-h preceding and the complete results can be found in Figure
S10.

Prediction performance in the real world

For the abovementioned test of model performance, each patient was labeled by the change in

SOFA score and the doctor's examination for infection at a threshold of 0.5. Data from the

control group and near onset of sepsis in the case group were included in the analysis. As

shown in Table 3, the AUCs for sepsis predictions in 1−5h preceding were 0.86−0.90.

Preceding hours	Accuracy	AUC	Sensitivity	Specificity

1	0.82	0.86	0.83	0.82
2	0.84	0.88	0.87	0.78
3	0.85	0.9	0.86	0.81
4	0.85	0.9	0.88	0.78
5	0.86	0.89	0.9	0.76

Table 3. The results of real-world data

In the real-world study, the threshold was increased to 0.7 to reduce the false alarm rate of sepsis warnings. Figure 3 illustrated examples of the prediction of sepsis by SEPRES over a random period (See Appendix 10 for more details). In the continuously early warning process of 67 patients admitted to the ICU, 22 septic patients and 29 non-septic patients were correctly predicted, whereas 17 non-septic patients and 6 septic patients were incorrectly predicted as false-positive and false-negative cases.

Figure 3: Some illustrative examples of prediction. Each subplot described the confidence index for multiple models (Y-axis) at the indicated time (X-axis). (i) The condition of the

patient aggravated in the early morning, with multiple organ dysfunction, and the patient was diagnosed with sepsis at noon. Our model prediction exceeded the warning threshold of 0.7 for the prediction at 9:00 AM. (ii) Despite the high SOFA score (7.0), there was no evidence of ΔSOFA ≥2 within 72 h. Consistently, the predictions were all lower than the threshold. (iii) Although the patient's SOFA score was stable at 6.0, our model made incorrect predictions of sepsis. (iv) The SOFA score showed an increase from 6.0 to 9.0 at 06:00 PM. In combination with evidence of infection, the patient was diagnosed with sepsis. However, the prediction was below the warning threshold.

Discussion

Machine learning has been considered a promising method for sepsis prediction in the ICU (6-16,20-22). Early diagnosis and timely management of septic patients can effectively improve the prognosis (34). However, sepsis may not be diagnosed in time in the clinic due to the day-night shift and inattention of medical staff. Therefore, an accurate and efficient early prediction system for sepsis at the bedside is urgently needed. In this study, we established an ICU bedside sepsis early warning system, SEPRES, to conduct real-time sepsis prediction for patients in the ICU by integrating IntelliVue Information Center, ventilators, Philips ICCA system, LIS, and HIS data. Although SEPRES could not provide a definitive basis for our therapeutic regime, the predicted probability of sepsis occurrence allows us to pay more attention to at-sepsis-risk patients.

Generalizability is the major obstacle to the deployment of machine learning into medical practice. Sufficiently large data size is crucial for the training of the machine learning model to achieve good performance. Moreover, the performance of the model derived from one cohort is always worsened when applied to external independent cohorts due to the differences in race, medical environment, disease type, and disease severity in different cohorts. In addition to this, as new tests and techniques are added, new features may help our

prediction task, but direct inclusion into existing machine learning models is usually not feasible. In our study, we deployed the transfer learning technique to improve the performance of our models in the target medical center. The transfer learning process effectively improved the prediction AUCs of LightGBM and MLP models on the HDRJH dataset, learns patterns from additional features, and showed consistent benefits across different data sizes of the target cohort. Hence, we argue that transfer learning might be a promising and feasible strategy to maintain the effectiveness of trans-center deployment of machine learning models. Transfer learning can also be used for similar but different prediction tasks, reducing the size requirements of the target dataset, and improving the training speed and the prediction performance (35). In our context, transfer learning can be used to predict different types of diseases, such as disseminated intravascular coagulation (DIC) or acute kidney injury (AKI).

Moreover, the lack of interpretability of these data-driven models prevents the practitioners to trust and accept these machine learning models in the clinic. In the present study, SHAP analysis as the interpretive tool helps medical practitioners identify top risk factors. what needs to be noted is fluid net balance and the use of antibiotics. Due to the difficulty of collecting the net balance data in most datasets, net balance has neither been considered as a feature for most machine learning models based on MIMIC datasets nor been analyzed as an important factor for sepsis prediction inference. Indeed, positive cumulative fluid balance has been reported to be an independent predictor of ICU mortality (32). Moreover, Lin et al have shown that patients with an early positive fluid balance have an increased risk of developing venous thromboembolism (36). Our SHAP analysis further emphasized the importance of

careful fluid management in critically ill patients. Therefore, we argue that including the net balance in the prediction model may improve not only the model performance but also the ICU clinical management. In addition, Our SHAP analysis results suggested that antibiotic use tends to increase the predicted occurrence of sepsis. Due to the uncertainty regarding antibiotic initiation in patients with suspected infection, the use of antibiotics is mostly empirical in ICU patients (37). It has been reported that inappropriate antibiotic treatment may accelerate the death of mice via increasing gut proliferation and systemic spreading of a multi-drug resistant (MDR) *Escherichia coli* strain (38). Moreover, the initial inappropriate broad-spectrum antibiotic therapy may promote the dissemination of multidrug-resistant bacteria (MDRB), increase opportunistic infection, and is associated with the poor prognoses of patients (39,40). Therefore, the inappropriate use of antibiotics may aggravate the severity of ICU patients and increase the probability of sepsis. It is urgently needed to improve the management of antibiotic therapy in ICU patients by optimizing reliable specimens and de-escalating antibiotics based on rapid diagnostic tools, therapeutic drug monitoring (TDM), and combined therapy.

SEPRES has certain limitations. First, we enrolled only patients who were non-septic during the entire period in the ICU as negative controls. The enrollment condition may be too pure to establish a model to predict sepsis, which may cause false-positive cases. Second, as we observed in consecutive case studies, patients diagnosed with sepsis shortly after being transferred to the ICU were difficult to be predicted by our model, which is probably due to that our model tends to give lower predictions when the collected data are limited. Finally, variables such as antibiotics and mechanical ventilation were incorporated by our model,

resulting in the influence of the model predictions by the subjective behavior of the doctor. However, considering that the use of antibiotics and mechanical ventilation are associated with the severity of the patient, it is essential to include them in our model. These limitations will be addressed in future work through diverse methods, including fine-grained labeling, inclusion of data collection from the ICU, and data augmentation. We also highlight that the application of transfer learning and interpretive tools can significantly improve the generalization and interpretability of the model but still possesses a distance to totally solve it.

Conclusions

In conclusion, the early prediction of sepsis occurrence by our SEPRES effectively guided medical practitioners to appropriately pay more attention to at-sepsis-risk patients, leading to early diagnosis of sepsis and more efficient ICU patient management. Our SHAP analysis suggests that we can place more emphasis on fluid net balance and the use of antibiotics. Moreover, with the help of the data integration system to collect necessary features and data, the workflow of SEPRES can be applied to disease warnings other than sepsis in the ICU, such as DIC and AKI. Furthermore, the proposed system can be applied to a larger number of medical centers with a certain number of records through transfer learning.

Acknowledgments

The authors acknowledge Shanghai Electric Group Co., Ltd. Central Academe for their support during the development of the data integration system.

Authors' contributions

WL, YT, LL, QC, RL, and Lin C conceived and designed the study. YT, LL, QC, RL, DC, HQ, and YH acquired the data. WL, Lin C, and Lai C implemented quality control of data and algorithms. WL, QC, RL, and Lai C had full access to and verified all data in the study. QC developed, trained, and applied machine-learning models. Lai C developed a data integration system. YT, LL, RL, DC, and HQ performed consecutive case studies. QC and RL prepared the first draft of the manuscript. WL, LL, and YT revised the manuscript. All authors contributed to the preparation of the manuscript.

Availability of supplementary resources

The MIMIC datasets generated and/or analyzed during the current study are available in the MIMIC repository, https://mimic.physionet.org/. The HDRJH dataset and RJ real-world data were approved for limited use by the Ruijin Hospital Ethics Committee, and were not publicly available. The code of the model inference was uploaded into GitHub under "SEPRES".

Funding

W.L. received funding from Shanghai Municipal Science and Technology Major Project (2018SHZDZX01), the ZHANGJIANG LAB, and the Science and Technology Commission of Shanghai Municipality (19JC1420101). The funders of the study had no role in the study design, data collection, data analysis, data interpretation, or writing of the report.
