distancing, lockdowns

ABSTRACT

Non-pharmaceutical interventions (NPIs), such as social distancing and contact tracing, have

been widely implemented during the COVID-19 pandemic. In addition to playing an

important role in suppressing transmission, NPIs influence pathogen evolution by mediating

mutation supply and altering the strength of selection for novel variants. However, it is

unclear how NPIs might affect the emergence of novel variants of concern that are able to

escape pre-existing immunity (partially or fully), are more transmissible, or cause greater

mortality. Here, we analyse a stochastic two-strain epidemiological model to determine how

the strength of NPIs affects the emergence of variants with similar or contrasting life-history

characteristics to the wildtype. We show that, while stronger and timelier NPIs generally

reduce the likelihood of variant emergence, it is possible for more transmissible variants

with high cross immunity to have a greater probability of emerging at intermediate levels of

NPIs. However, since one cannot predict the characteristics of a variant, the best strategy to

prevent emergence is likely to be implementation of strong, timely NPIs.

AUTHOR SUMMARY

During the COVID-19 pandemic, a wide range of non-pharmaceutical interventions,

including mask wearing, quarantine, isolation, and lockdowns, have been used by

governments around the world to suppress virus transmission. Although considerable

efforts have been made to understand how such interventions affect transmission, much

less attention has been paid to their effects on pathogen evolution. While vaccines are well-

known to affect virus evolution, non-pharmaceutical interventions also influence mutation

supply and the strength of selection, and hence play a key role in the emergence of novel

variants. Here, we use a relatively simple mathematical model to explore how non-

pharmaceutical interventions during an epidemic affect the emergence of a novel variant of

a pathogen. We show that in general, it is important to implement effective transmission-

reducing public health measures in a timely manner to prevent the emergence of novel

variants, which may be more transmissible, more deadly, or able to escape immunity.

INTRODUCTION

Understanding the impact of interventions for infectious disease control on pathogen evolution is a major challenge at the interface of public health and evolutionary biology [1–3]. During the COVID-19 pandemic, a wide range of non-pharmaceutical interventions (NPIs) have been implemented across the world, including social distancing, improved hygiene practices, lockdowns, quarantining exposed or isolating infected individuals, and contact tracing. Such measures have been credited with reducing cases and bringing epidemics under control, both prior to and in conjunction with vaccine rollouts [4–7]. Recently, there has been renewed interest in the effects of vaccination programmes on pathogen evolution and subsequent transmission. This includes the potential for more transmissible or more virulent variants, or those that are able to escape naturally- or vaccine-induced immunity [8–13]. However, while the impact of vaccination on SARS-CoV-2 evolution has been the subject of significant recent interest, there has been relatively little attention directed at the effects of NPIs on the emergence on novel variants of concern [1,14].

The emergence of a novel variant occurs in two stages. First, the variant must be generated through mutation or recombination ("appearance"). Mutation supply governs the appearance of a new variant and depends on the rate at which the pathogen replicates in the host population (determined by the number of infected hosts [10]), the mutation rate, and the number of mutations required to generate the variant. By reducing opportunities for transmission, NPIs effectively lower the rate at which the pathogen replicates, and hence lower the mutation supply. NPIs should therefore always make the appearance of novel variants less likely.

If a variant does appear, then the second stage for emergence requires sustained

transmission between hosts ("establishment" – Fig. 1a). It should be noted that many

variants are likely to appear that have little or no impact on pathogen transmission or

virulence [1,15]. Variants may appear but remain undetected as they are unable to become

established due to selection (if the variant is less fit than the wildtype) [16] or stochastic

extinction (if by chance the variant dies out before it can infect many hosts) [17–19]. NPIs

are likely to have more complex effects on the establishment phase as they mediate both

the strength of selection and the likelihood of stochastic extinction. For example, stronger

NPIs will slow the rate at which a variant can spread and will increase the likelihood of

stochastic extinction, but will also change how immunity accumulates in the host

population. Increased immunity to the wildtype virus could strengthen selection for the

variant.

Here, we analyse a stochastic model of pathogen evolution to explore the effects of NPIs on

the emergence of novel variants. We show how the strength and timing of NPIs, along with

the life-history characteristics of the variant, affect its emergence and impact on the host

population.

METHODS

To explore the key factors underlying the emergence of novel variants in a simple setting,

we model infectious disease dynamics in a well-mixed, homogeneous host population over

a relatively short period, ignoring host births and natural mortality for simplicity (see Fig. 1b

for model structure). We restrict our model to two strains, a wildtype (w) and a variant (v),

whose transmission rates are both equally affected by NPIs, as determined by the

parameter r ($0 \le r \le 1$). We assume that, for each strain, the baseline transmission rate is

β_i ($i \in \{w, v\}$), the infection fatality rate (IFR) for single infections is α_i (i.e. a proportion α_i

of individuals die from infection, on average), and the average infectious period is $1/\gamma$.

Following a primary infection, an individual is assumed to be fully immune to the strain by

which they were infected, and to have acquired partial cross-immunity, c, to the other

strain ($0 \le c \le 1$). Thus, when $c = 0$ there is no cross-immunity between strains and when

$c = 1$ there is full cross-immunity. Immunity is assumed to act to reduce a host's

susceptibility to reinfection [20]. We assume that the variant differs from the wildtype at a

single genetic locus, and that mutations occur between strains at rate ξ, leading to

coinfections by both strains. The IFR for coinfections is assumed to be the average of the

wildtype and variant, $\alpha_C = \frac{1}{2}(\alpha_w + \alpha_v)$.

At time, t, we use the following notation: S_t is the number of hosts that are susceptible to

both the wildtype and the variant (initially all individuals are susceptible to both strains), I_t^i

is the number of primary infections by strain i, I_t^{ij} is the number of secondary infections by

strain j following recovery from primary infection by strain i, C_t is the number of

coinfections, R_t^i is the number of individuals who have recovered from a primary infection

by strain i (and are immune to strain i), and R_t the number of individuals who have

recovered from both strains (and are therefore immune to both strains). In the absence of

NPIs, the per-capita force of infection on fully susceptible hosts for strain i is denoted $\lambda_t^i =$

$\beta_i(I_t^i + I_t^{ji} + C_t)$ ($i \ne j$ throughout). We assume that NPIs are triggered (and remain in

place for the rest of a simulation) when the total disease prevalence, $\tilde{I}_t = (I_t^w + I_t^v + I_t^{wv} +$

$I_t^{vw} + C_t)/N$, first exceeds a threshold of ϵ. Primary infections by strain i therefore occur at

per-capita rate λ_t^i before NPIs are triggered and $\lambda_t^i(1-r)$ after NPIs are triggered. Similarly,

secondary infections and coinfections (not arising from mutation) occur at per-capita rates

$\lambda_t^i(1-c)$ and $\lambda_t^i(1-r)(1-c)$ before and after NPIs are triggered, respectively. The

effective (or time-varying) reproduction number [21,22] of strain i at time t in the absence

of restrictions, $\mathcal{R}_t^i$, is therefore:

$$\mathcal{R}_t^i = \frac{\beta_i}{\gamma}\left(S_t + (I_t^j + R_t^j)(1-c)\right) \qquad (1)$$

We run simulations of the model using the direct method version of the Gillespie stochastic

simulation algorithm [23] using a population size of $N = 100{,}000$ and initial condition

$\{S_0, I_0^w, I_0^v\} = \{N - 100, 100, 0\}$, with 1,000 simulations per parameter set. Since here we

are only interested in the emergence of a new variant, we fix the following parameters as

they do not qualitatively change our results: $\alpha_w = 0.005$, $\xi = 5 \times 10^{-5}$, $\gamma = 1/5$, $\beta_w =$

$\mathcal{R}_0^w \gamma / N$, and $\mathcal{R}_0^w \approx 3$. We choose β_v such that the variant is less $\left(\frac{\beta_v}{\beta_w} < 1\right)$, equally

$\left(\frac{\beta_v}{\beta_w} = 1\right)$, or more $\left(\frac{\beta_v}{\beta_w} > 1\right)$ transmissible than the wildtype. We also vary the threshold for

triggering NPIs ($\epsilon \in \{0, 0.2\}$), the level of cross-immunity between the wildtype and variant

($0 \le c \le 1$), the strength of NPIs ($0 \le r \le 1$), and the relative IFR of the variant

$\left(\frac{\alpha_v}{\alpha_w} \in \{1,2,3\}\right)$. We define emergence by concluding that the variant has emerged if the

frequency of infections caused by the variant exceeds 10% at any time during a simulation.

Simulations are terminated when the number of hosts infected reaches 0.

Figure 1 – Schematics demonstrating the phenomenon of novel variant establishment and

the model used to explore the factors underlying novel variant emergence (appearance

followed by establishment). (a) Establishment. Following appearance in the population, the

variant may either establish and spread around the population or fail to establish (either

because it is less fit than the wildtype or due to stochastic extinction, shown by the thin blue

line along the x-axis). (b) Model schematic. Arrows show transitions between classes, as

described in the main text.

RESULTS

WHEN IS THE VARIANT FITTER THAN THE WILDTYPE?

We consider a scenario in which the variant is initially rare relative to the wildtype. The

variant is fitter than the wildtype when $\mathcal{R}_t^v > \mathcal{R}_t^w$, which requires:

145
$$\frac{\mathcal{R}_t^v}{\mathcal{R}_t^w} = \frac{\beta_v \left(S_t + (I_t^w + R_t^w)(1-c) \right)}{\beta_w \left(S_t + (I_t^v + R_t^v)(1-c) \right)}$$

146
$$\approx \frac{\beta_v}{\beta_w} \left(1 + \frac{(I_t^w + R_t^w)(1-c)}{S_t} \right) > 1 \tag{2}$$

Hence, a variant is always fitter when it is at least as transmissible as the wildtype and there

is not full cross immunity ($c < 1$). However, a less transmissible variant may also be fitter

provided the wildtype has already infected a sufficient proportion of the population and

there is not full cross immunity. Clearly, when $c < 1$ the fitness of the variant will increase

relative to the wildtype as the pool of susceptible hosts for the latter is depleted. Note that

NPIs do not affect whether a variant is fitter than the wildtype since there is no differential

effect on transmission. NPIs will, however, affect mutation supply (and hence the

appearance of the variant) and the rate at which the variant can spread (establishment).

TIMELY NPIS ($\epsilon = 0$)

We initially consider the case when NPIs are triggered immediately ($\epsilon = 0$; Fig. 2) and are

sufficiently strong to prevent the wildtype from initially spreading $\left(r > 1 - \frac{1}{\mathcal{R}_0^w} \right)$. Unless the

mutation rate is very high, it is unlikely that the variant will appear before the wildtype is

driven extinct. Thus, the probability of a variant emerging is close to 0 whenever $r > 1 - \frac{1}{\mathcal{R}_0^w}$

regardless of transmissibility or cross immunity (Fig. 2g-i). When $r < \min\left\{1 - \frac{1}{\mathcal{R}_0^w}, 1 - \frac{1}{R_t^v}\right\}$,

the probability of a variant emerging depends on the relative transmissibility of the variant,

the strength of cross immunity, and the strength of NPIs. When cross immunity and NPIs are

both relatively weak, there is a high probability of variants emerging (Fig. 2g-i). This is

because there is a high mutation supply (weak restrictions) to generate the variant and a

large pool of susceptible individuals to exploit.

When the variant is less or equally as transmissible as the wildtype, there is an inverse effect

of cross immunity and NPIs on the probability of the variant emerging: weaker NPIs require

stronger cross immunity, and vice versa, to prevent the variant emerging (Fig. 2g-h). When

the variant is sufficiently more transmissible, however, it has a high probability of emerging

even when cross immunity is strong (Fig. 2i). Most notably, the variant is more likely to

emerge for intermediate NPIs when cross-immunity is very high or complete ($c \approx 1$). This is

because when NPIs are weak ($r \ll 1$), there is a large outbreak of the wildtype, which leads

to a high mutation supply but also rapidly depletes the pool of hosts for the variant due to

cross-immunity (Fig. 3a, d). Thus, while a variant is likely to appear, it is unlikely to spread

widely in the population due to herd immunity [24]. When NPIs are stronger (but not too

strong) the wildtype causes a smaller outbreak, leading to a lower build-up of cross

immunity in the population while still maintaining a sufficient mutation supply for the

variant to appear with high probability (Fig. 3b, e). This creates just the right conditions to

allow the variant to sweep into the population. As a result of this phenomenon, it is possible

for total deaths (for both strains) to peak at intermediate NPIs when the variant is both

more transmissible and more deadly than the wildtype (Fig. 4).

Figure 2 – Effects of the strength of NPIs (r), strength of cross immunity (c), and relative

transmissibility of the variant (β_v/β_w; as indicated at the top of each column) on: (a)-(c)

median proportion of hosts infected by the variant; (d)-(f) median total deaths (per 100k)

for both strains; and (g)-(i) the probability of the variant emerging (reaching a frequency of

at least 0.1). Data are shown for 100 simulations of each parameter combination. The NPI

trigger threshold is $\epsilon = 0$ (i.e. NPIs are triggered at the start of each simulation). Other

parameters as described in the main text, with: $\alpha_v/\alpha_w = 1$.

Figure 3 – Simulations with full cross immunity and a more transmissible variant $\left(\frac{\beta_v}{\beta_w} = 1.5\right)$

for different levels of NPIs: (a, d) no NPIs ($r = 0$); (b, e) intermediate NPIs ($r = 0.5$); (c, f)

strong NPIs ($r = 0.75$). (a-c) Proportion infected by the wildtype (blue) and by the variant

(red). (d-f) Frequency of the variant. Simulations were terminated when the pathogen was

driven extinct. Other parameters as described in the main text, with: $\alpha_v/\alpha_w = 1$ and $\epsilon = 0$.

Figure 4 – Effects of NPIs (r) and the relative virulence (IFR) (α_v/α_w) of a more

transmissible variant $(\beta_v/\beta_w = 1.5)$ on total deaths (per 100k) when there is full cross

immunity $(c = 1)$ and NPIs are timely $(\epsilon = 0)$. Plots show the median (black) along with the

upper and lower quartiles (grey) over 100 simulations. Other parameters as described in the

main text.

DELAYED NPIS $(\epsilon = 0.2)$

We now consider the case where NPIs are delayed until 20% of the population is infected

(Fig. 5). There are three notable effects of delaying NPIs. First, since NPIs are delayed, a non-

negligible number of deaths now occur over the full range of NPI strengths (Fig. 5d-f).

Second, as the initial mutation supply is no longer curtailed by NPIs, variants can emerge

during the early stages for $r > 1 - \frac{1}{R_0^w}$ (Fig. 5i). Third, more transmissible variants which

experience sufficiently high cross immunity with the wildtype ($c \approx 1$) are no longer likely to

emerge at intermediate NPIs (compare Fig. 2i and Fig. 5i). This is because cross immunity

accumulates in the population to prevent the more transmissible variant from establishing.

Consequently, there is no effect of varying the relative mortality on total deaths when NPIs

are delayed for a more transmissible variant with high cross immunity (Fig. S1).

Figure 5 – Effects of the strength of NPIs (r), strength of cross immunity (c), and relative

transmissibility of the variant (β_v/β_w); as indicated at the top of each column) on: (a)-(c)

median proportion of hosts infected by the variant; (d)-(f) median total deaths (per 100k)

for both strains; and (g)-(i) the probability of the variant emerging (reaching a frequency of

at least 0.1). Data are shown for 100 simulations of each parameter combination. The NPI

trigger threshold is $\epsilon = 0.2$ (i.e. NPIs are triggered when 20% of the host population is

infected by either strain). Other parameters as described in the main text, with: $\alpha_v/\alpha_w = 1$.

DISCUSSION

The emergence of novel variants depends on the interaction between mutation supply and the strength of selection, both of which are influenced by NPIs. Here, we have shown how NPIs and the stage of an epidemic at which they are triggered affect the emergence of novel variants with a range of life-history characteristics. Although stronger, earlier implementation of NPIs generally reduces the likelihood that a novel variant will emerge, more transmissible variants that exhibit a high degree of cross immunity with the wildtype may be most likely to emerge when NPIs are enacted early but are of insufficient strength to drive the wildtype extinct quickly (Fig. 2i, Fig. 3b). This echoes a theoretical result for vaccination, which suggests that imperfect vaccination may provide the optimal conditions for vaccine-escape variants to emerge [8,25]. This is because imperfect vaccination can allow a significant mutation supply while also exerting selective pressure for vaccine-escape variants.

Here, we found a similar result for NPIs. When NPIs are weak, a large outbreak of the wildtype can occur. This allows a variant to appear (high mutation supply) but prevents it from spreading widely due to the accumulation of cross immunity in the host population (the variant cannot establish). When NPIs are at an intermediate level, however, there may be sufficient mutation supply to allow the variant to appear but insufficient accumulation of cross immunity from the wildtype. The higher transmissibility of the variant then facilitates its establishment. If the variant is also sufficiently more virulent, then it is possible that this will increase the overall number of deaths (Fig. 4). These patterns at high cross immunity disappear when NPIs are delayed, but in general the variant is able to emerge over a wider set of conditions compared to when NPIs are introduced quickly.

While it is possible that intermediate strength or timely NPIs may occasionally lead to more

negative outcomes than weaker or delayed NPIs as described above, we note that this

requires the variant to have a specific set of characteristics. Since it is challenging to predict

the phenotypic characteristics of novel variants, we contend that the optimal strategy to

prevent variants of concern arising is almost always to ensure that NPIs are strong and

implemented in a timely fashion. If this is done, then the mutation supply is constrained,

preventing novel variants from appearing in the first place.

Of course, when deciding to implement strong and timely NPIs, a range of factors must be

accounted for. The possibility that the wildtype might fade out without invading the host

population in the absence of NPIs could be considered [26,27]. In that case, it may be

unnecessary to introduce costly NPIs [28]. On the other hand, it may be impossible to

contain or eradicate a pathogen, even if strong NPIs are introduced [5]. In that scenario,

potential negative non-disease health outcomes of NPIs should be considered, particularly if

NPIs are maintained over long periods. Comparing the costs and benefits of a range of

public health measures is an essential area of research [29,30]. As we have demonstrated,

potential evolutionary consequences of different NPIs could be an important component of

such analyses.

In order to explore the potential effects of NPIs on the emergence of pathogen variants, we

made several simplifying assumptions in our modelling approach. First, we assumed that

there is no differential effect of NPIs on the wildtype and the variant transmission rates.

While this is often likely to be true, it is possible that NPIs may affect some variants more

than others. For example, if symptomatic people are more likely to be identified and

isolated, then selection may favour variants that cause more asymptomatic infections or

that have a longer incubation period. Similarly, if individuals are isolated following contact

tracing, then variants with shorter generation times may be favoured. Second, our model

does not include population heterogeneity or contact structure, both of which affect

pathogen transmission and the emergence of variants. If, for example, some individuals are

less likely to adhere to NPIs, then it may be easier for new variants to emerge. This effect

may be particularly pronounced if those individuals belong to specific groups in a population

within which transmission may occur. Third, for simplicity we assumed that the wildtype

and variant only differed by one mutation at a single genetic locus with potential pleiotropic

effects on antigenicity, transmissibility, and virulence. In reality, genetic and phenotypic

landscapes are complex, with multiple mutations sometimes required to transition between

variants, some of which may be initially neutral or deleterious due to epistasis. For example,

the B.1.1.7 SARS-CoV-2 variant that emerged in the United Kingdom in late 2020, and the

B.1.351 variant that emerged in South Africa, were found to have unusually large numbers

of genetic changes, particularly in the spike protein [31,32]. Finally, we did not model the

effects of vaccination programmes on the potential for new variants to emerge, as these

have been considered elsewhere [8–11,33].

Despite these simplifications to our model, our results allowed us to demonstrate important

principles about the effects of NPIs on the emergence on variants and are likely to be

qualitatively robust with respect to the effects of NPIs. For instance, some differential

effects of NPIs are simply equivalent to altering the transmissibility of the variant.

Population heterogeneity and contact structure both affect pathogen transmission, and so

are also likely to affect the initial spread of variants. We would therefore expect the

emergence probability to increase in some cases and decrease in others. However, the

qualitative patterns shown here are unlikely to change. Finally, increasing the genetic and

phenotypic landscape will tend to make it more difficult for variants to emerge. This is

because a greater number of mutations, some of which may be deleterious due to epistasis,

are likely to be required to generate the variant. One could crudely model this by reducing

the mutation supply in our model to mimic the lower rate of accumulating multiple

mutations, which would quantitatively, but not qualitatively, change our results.

In conclusion, NPIs have significant impacts on the emergence of novel variants by

mediating both the mutation supply and the strength of selection. Although stronger NPIs

generally reduce the probability that a new variant of concern will emerge, there are

circumstances – namely, when cross immunity is high and the variant is more transmissible

– where NPIs of intermediate strength can increase variant emergence, potentially leading

to a higher level of mortality. However, this requires a very particular set of circumstances

and one cannot predict where a variant will emerge in phenotype space (i.e. its

transmissibility, virulence, and level of cross immunity). The optimal strategy to prevent

variants emerging is therefore to ensure that NPIs are sufficiently strong to drive the

wildtype extinct, thereby cutting off the mutation supply.
