34

35 **Abstract**

36 **Objectives:** The use of monoclonal antibody for COVID-19 showed conflicting results in  
37 prior studies and its efficacy remains unclear. We aimed to comprehensively  
38 determine the efficacy and safety profile of monoclonal antibodies in COVID-  
39 19 patients.

40 **Methods:** Sixteen RCTs were analyzed using RevMan 5.4 to measure the pooled  
41 estimates of risk ratios (RRs) and standardized mean differences (SMDs) with  
42 95% CIs.

43 **Results:** The pooled effect of monoclonal antibodies demonstrated mortality risk  
44 reduction (RR=0.89 (95%CI 0.82-0.96),  $I^2=13%$ , fixed-effect). Individually,  
45 tocilizumab reduced mortality risk in severe to critical disease (RR=0.90  
46 (95%CI 0.83-0.97),  $I^2=12%$ , fixed-effect)) and lowered mechanical ventilation  
47 requirements (RR=0.76 (95%CI 0.62-0.94),  $I^2=42%$ , random-effects).  
48 Moreover, it facilitated hospital discharge (RR=1.07 (95%CI 1.00-1.14),  
49  $I^2=60%$ , random-effects). Meanwhile, bamlanivimab-etesevimab and REGN-  
50 COV2 decrease viral load ((SMD=-0.33 (95%CI -0.59 to  
51 -0.08); (SMD=-3.39 (95%CI -3.82 to -2.97)). Interestingly, monoclonal  
52 antibodies did not improve hospital discharge at day 28-30 (RR=1.05 (95%CI  
53 0.99-1.12),  $I^2=71%$ , random-effects) and they displayed similar safety profile  
54 with placebo/standard therapy (RR=1.04 (95%CI 0.76-1.43),  $I^2=54%$ , random-  
55 effects).

56 **Conclusion:** Tocilizumab improved hospital discharge and reduced mortality as well as the  
57 need for mechanical ventilation, while bamlanivimab-etesevimab and REGN-  
58 COV2 reduced viral load in mild to moderate outpatients. In general,  
59 monoclonal antibodies are safe and should be considered in severe to critical  
60 COVID-19 patients.

## 63 INTRODUCTION

64 Since December 2019, a novel coronavirus disease (COVID-19) firstly discovered in  
65 Wuhan, China has spread globally and profoundly affected various aspects of life (Li et al.,  
66 2020). The viral infectious disease is caused by SARS-CoV-2; an enveloped, positive-sense,  
67 single-stranded genomic ribonucleic acid (+ssRNA) virus from the group of *Betacoronavirus*  
68 in the family of *Coronaviridae* (Hu et al., 2021). In the lungs, SARS-CoV-2 binds to  
69 angiotensin converting enzyme type-2 (ACE-2) receptors at the membrane of pulmonary  
70 alveolar cells type-2 and undergoes endocytosis. Subsequently, the interaction of viral  
71 antigen with RIG-I-like receptors (RLRs) activates the host immune system as an effort to  
72 eliminate the virus from the body (Hertanto et al., 2021), predisposing to the clinical  
73 presentations of COVID-19 patients, ranging from asymptomatic or mild up to severe disease  
74 state with pneumonia and acute respiratory distress syndrome that can ultimately lead to  
75 death (Lai et al., 2020).

76 The development of optimal and effective therapies for COVID-19 is essential to  
77 minimize COVID-19 morbidity and mortality (Lu, 2020; Li and De Clercq, 2020). Several  
78 components of the virus and host immune system have been identified as potential targets in  
79 COVID-19 management. A previous study reported that the SARS-CoV-2 S2 protein was  
80 important for viral entry and thought to be a potential target for neutralizing antibody (Walls  
81 et al., 2020). Moreover, the SARS-CoV-2 infection could trigger a hyperactive immune  
82 response, leading to cytokine release syndrome (CRS) or cytokine storm (Hertanto et al.,  
83 2021). Among numerous proinflammatory cytokines involved in CRS, interleukin (IL)-6 is  
84 one of the most critical and has been associated with a poor prognosis (Zhang et al., 2020a;  
85 Zhang et al., 2020b; Zhao, 2020). Therefore, the inhibition of IL-6 (e.g., by preventing the  
86 binding to its receptors) could prevent the occurrence of CRS and lower the severity of the  
87 disease. Moreover, complement C5a and white blood cells (i.e., neutrophil and monocytes)  
88 were detected in the bronchoalveolar lavage fluid (BALF) of COVID-19 patients, supporting  
89 the chemoattraction role of C5a in lungs-derived C5aR1-expressing cells; which is  
90 responsible for cell damage and ARDS (Carvelli et al., 2020). Of note, C5a is one of the  
91 major drivers for complement-mediated inflammation that rapidly responds to pathogens and  
92 cellular injury (Woodruff and Shukla, 2020).

93 Monoclonal antibody is one of the proposed therapeutic options for COVID-19. Anti-  
94 SARS-CoV-2 monoclonal antibodies are among the latest investigational COVID-19  
95 treatments granted with emergency use authorization (EUA) from the United States Food and

96 Drug Administration (FDA). Briefly, monoclonal antibodies recognize one epitope of an  
97 antigen while polyclonal antibodies recognize multiple epitopes (Lipman et al., 2005). The  
98 variable region can be modified to target specific molecules, including the S2-protein,  
99 cytokines, and cytokine receptors. Among 5 Antibody isotypes—IgA (subclasses IgA1 and  
100 IgA2), IgE, IgD, IgM, and IgG (subclasses IgG1, IgG2, IgG3 and IgG4)—IgG is commonly  
101 selected for therapeutic purposes due to its strong binding affinity to an antigen and its Fc  
102 receptor, supported by its long serum half-life (Chames et al., 2009; Lu, 2020). As the  
103 consequence, the administration of neutralizing monoclonal antibody targeting SARS-CoV-2  
104 spike proteins allows the inhibition of virus attachment to human ACE-2 receptors, thus  
105 inhibits viral entry (Tian et al., 2020). To prevent complement system activation triggered  
106 during SARS-CoV-2 infection, a recent study proposed the use of monoclonal antibody  
107 against C5a (anti-C5a) (Woodruff and Shukla, 2020). Among available monoclonal  
108 antibodies for COVID-19, anti-IL-6 receptors and anti-SARS-CoV-2 are widely studied in  
109 clinical trials (Yang et al., 2020; Patel et al., 2021).

110 Nonetheless, the efficacy and safety of this pharmacological agent remain  
111 controversial (FDA, 2020; Patel et al., 2021). Moreover, at present, the application of  
112 monoclonal antibody as a therapeutic agent in COVID-19 shows conflicting results in prior  
113 studies, demanding further investigations. Thus, this meta-analysis aims to assess the  
114 previously reported efficacy and safety of monoclonal antibodies on clinical and laboratory  
115 outcomes and its safety profile in COVID-19 patients.

116

## 117 **MATERIALS AND METHODS**

### 118 **Search Strategy**

119 The PubMed (MEDLINE), ScienceDirect, Cochrane Library, Proquest and Springer  
120 databases were systematically searched from January 25 until February 5, 2021, without any  
121 limitation of publication year. We also performed manual searches, extended from February 5  
122 to March 5, 2021, through MedRxiv and citation searching to get evidence from unpublished  
123 data and retrieve potential articles without missing any additional eligible studies. The  
124 following keywords were used: “(COVID-19) AND ((Monoclonal Antibody) OR  
125 (Neutralizing Antibody) OR (Serotherapy)) AND ((Viral Load) OR (Oxygen) OR (Duration)  
126 OR (Mortality) OR (Inflammation))”. Additional details about the search strategy are  
127 available in *Supplementary Materials*.

## 128 **Data Collection**

129 The title and abstract of the articles were screened by IAW and NRP. Duplications  
130 were removed using the Mendeley reference manager. We independently screened the title  
131 and abstract of all retrieved studies based on the following eligibility criteria: (1) participants  
132 confirmed at any clinical stage of COVID-19 with/without other comorbidities; (2) adult ( $\geq 18$   
133 years) male/female study population; (3) the study involved monoclonal antibody treatments  
134 of interest; (4) the study compared the intervention group with control (placebo or/and  
135 standard of care or combination therapy); (5) the study evaluated efficacy (i.e. mortality, need  
136 for mechanical ventilation, hospital discharge, virologic outcomes) or safety outcomes  
137 (serious adverse events); (6) study type was randomized controlled trial (RCT).

## 138 **Data Extraction and Quality Assessment**

139 IAW, NRP, and DSB independently extracted relevant data using the standardized  
140 form. The following information was extracted: first author's name and publication year,  
141 study design, country, sample size, age, disease severity, dosage and administration of  
142 monoclonal antibodies, types of comparison, and outcomes (all-cause mortality, need for  
143 mechanical ventilation, hospital discharge at day 28-30, change of viral load, and serious  
144 adverse events). Serious adverse events were defined as any untoward medical occurrence  
145 that are potentially related to monoclonal antibody treatment.

146 The studies were classified into "low risk of bias," "some concerns," or "high risk of  
147 bias" according to the Cochrane risk of bias tool for randomized trial (RoB ver.2) (Sterne et  
148 al., 2019). Any discrepancies were consulted with an expert and resolved by discussion until  
149 reaching consensus. The Grading of Recommendation Assessment, Development, and  
150 Evaluation (GRADE) system was used to evaluate the quality of evidence of the findings  
151 (Brignardello-Petersen et al., 2018; Puhan et al., 2014).

## 152 **Statistical Analysis**

153 Primary analyses were carried out using the Review Manager version 5.4 (The  
154 Cochrane Collaboration). Pooled risk ratios (RRs) for dichotomous outcomes were evaluated  
155 using Mantel-Haenszel method. Standardized mean differences (SMDs) of continuous  
156 outcomes were pooled using inverse variance.  $I^2$  test was used to quantify heterogeneity  
157 between studies, with values  $I^2 > 50\%$  represents moderate-to-high heterogeneity. If the value  
158 of  $I^2$  statistics was  $< 50\%$  or the  $p$ -value was  $> 0.1$ , the fixed-effects model could be applied;  
159 otherwise, the random-effects model would be used. Begg's funnel plot and Egger's test were

160 performed for publication bias analysis, and if present, trim-and-fill method was performed.  
161 All statistical analysis with a  $p$ -value<0.05 was considered statistically significant.

162 Subgroup analyses were done on monoclonal antibody types and disease severity for  
163 mortality risk, and monoclonal antibody types for the other outcomes. Leave-one-out  
164 sensitivity analysis was conducted to find the source of statistical heterogeneity and  
165 demonstrate how each study affected the overall result. Fixed-effects and random-effects with  
166 different tau estimators (DL, SJ, and HKSJ) were performed for sensitivity analysis using R  
167 version 4.0.5 to find the robustness of pooled data (see *Supplementary Materials*).

168

## 169 **RESULTS**

### 170 **Study characteristics**

171 We identified 6032 and 7310 studies through primary database and manual searching,  
172 respectively. After duplication removal, we screened potentially relevant studies and obtained  
173 228 studies to be checked for eligibility. Some studies were excluded due to the reasons  
174 documented in PRISMA diagram (*Figure 1*).

175 Among 16 RCTs, the REMAP-CAP trial (Gordon et al., 2021) was split into two  
176 separate intervention groups: the tocilizumab and sarilumab groups. In total, there were 8857  
177 participants included in the meta-analysis, consisted of 4700 and 4157 participants in the  
178 intervention and control groups, respectively. The characteristics and outcomes summary for  
179 each study, RoB ver.2 assessment, and the certainty of evidence of findings reported using  
180 GRADE system are presented in *Supplementary Tables*.

### 181 **MORTALITY**

#### 182 **All-cause mortality**

183 All-cause mortality was examined from 16 RCTs with a total of 8857 patients. Monoclonal  
184 antibody was associated with a lower mortality risk (RR=0.89 (95%CI 0.82-0.96),  $I^2=3%$ ,  
185 fixed-effects). Subsequently, subgroup analyses on the disease severity and monoclonal  
186 antibody types were conducted, however only tocilizumab and sarilumab therapies for  
187 severe-critical COVID-19 patients were pooled, due to limited studies available (*Figure 2*).

#### 188 **Tocilizumab in severe-critical COVID-19**

189 Patients with severe-critical COVID-19 receiving tocilizumab displayed a lower mortality  
190 risk (RR=0.90 (95%CI 0.83-0.97),  $I^2=12%$ , fixed-effect). RECOVERY trial contributed to

191 the most weight in this meta-analysis (71.1%), and 82.3% in tocilizumab arm and 82.2% in  
192 standard therapy arm receiving corticosteroid (pooled RR=0.87 (95%CI 0.80-0.95),  $I^2=14\%$ ,  
193 fixed-effects). Omitting this trial did not change the direction of effect, although it impaired  
194 the statistical significance (RR=0.92 (95%CI 0.78-1.10),  $I^2=25\%$ , fixed-effects). Meanwhile,  
195 TOCIBRAS trial mainly contributed to the statistical heterogeneity. Excluding this study  
196 from the analysis provided a more consistent result (pooled RR=0.89 (95%CI 0.82-0.96),  
197  $I^2=0\%$ ). At last, Funnel plot and Egger's test did not show any publication bias.

### 198 **Sarilumab in severe-critical COVID-19**

199 In severe to critical COVID-19 patients treated with sarilumab, the pooled effect was  
200 evaluated using two studies: EudraCT and REMAP-CAP trials (RR=0.74 (95%CI 0.48-1.14),  
201  $I^2=2\%$ , fixed-effect). Numerically, the RR was lower than that of tocilizumab, but it did not  
202 reach statistical significance. Egger's test cannot be performed because there were only two  
203 studies included in the analysis.

### 204 **THE NEED FOR MECHANICAL VENTILATION**

205 Ten RCTs consisted of 6061 patients were examined (**Figure 3**). Only studies involving anti-  
206 IL-6R antibodies reported mechanical ventilation outcome. All participants were in severe-  
207 critical disease, except for the participants from COVINTOC trial who were in moderate-  
208 severe state. Although IL-6R did not demonstrate a reduction of mechanical ventilation  
209 requirements (RR=0.76 (95%CI 0.61-0.96,  $I^2=49\%$ , random-effects), subgroup analyses  
210 revealed that tocilizumab significantly reduced the need for mechanical ventilation (RR=0.76  
211 (95%CI 0.62-0.94),  $I^2=42\%$ , random-effects), but not sarilumab (RR=0.76 (95%CI 0.21-  
212 2.78),  $I^2=87\%$ , random-effects). We also found that EMPACTA trial was the source of  
213 heterogeneity in the tocilizumab subgroup. However, omitting this study yielded a similar  
214 result (RR=0.81 (95%CI 0.72-0.91),  $I^2=0\%$ , fixed-effects). No publication bias was detected  
215 from the funnel plot and Egger's test.

### 216 **HOSPITAL DISCHARGE AT DAY 28-30**

217 Eleven RCTs consisted of 7490 patients were examined (**Figure 4**). The overall effect of the  
218 interventions on hospital discharge at day 28-30 showed no significant difference (RR=1.05  
219 (95%CI 0.99-1.22),  $I^2=71\%$ , random-effects). Patients in tocilizumab and sarilumab  
220 subgroups had severe-critical disease, while patients receiving spike-protein antibodies were  
221 in moderate-severe COVID-19. Subsequently, subgroup analyses for sarilumab and  
222 tocilizumab were performed and only tocilizumab significantly increased the rate of hospital

223 discharge (RR=1.07 (95%CI 1.00-1.14),  $I^2=60\%$ , random-effects). The  $p$ -value in 4  
224 significant figures was 0.0498, therefore it reached statistical significance. The funnel plot  
225 and Egger's test did not indicate any publication bias.

## 226 **CHANGE OF VIRAL LOAD**

227 Two RCTs consisted of 896 patients with bamlanivimab monotherapy (*Figure 5*) indicated  
228 that bamlanivimab alone did not reduce viral load at day 11 (SMD=-0.07 (95%CI -0.21 to  
229 0.07),  $I^2=44\%$ , fixed-effect), in contrast to the combination of bamlanivimab and etesevimab  
230 (SMD=-0.33 (95%CI -0.59 to -0.08)). In addition, REGN-CoV2 significantly reduced viral  
231 load at day 7 (SMD=-3.39 (95%CI -3.82 to -2.97)). However, only two studies included into  
232 the analysis, thus Egger's test could not be performed.

## 233 **SERIOUS ADVERSE EVENTS**

234 In 16 RCTs of 8897 patients, the overall safety of monoclonal antibody did not differ from  
235 placebo/standard therapy (RR=1.04 (95%CI 0.76-1.43),  $I^2=54\%$ , random-effects) (*Figure 6*),  
236 as well as the subgroup analyses performed for anti-spike-protein (RR=1.00 (95%CI 0.67-  
237 1.49)  $I^2=29\%$ , fixed-effect), tocilizumab (RR=0.96 (95%CI 0.79-1.18),  $I^2=72\%$ , random-  
238 effects) and sarilumab (RR=1.12 (95%CI 0.74-1.70),  $I^2=0\%$ , fixed-effect). Interestingly, the  
239 CORIMUNO-TOCI 1 trial reported that tocilizumab was significantly safer than  
240 placebo/standard therapy. On the contrary, the EMPACTA trial showed that tocilizumab was  
241 more harmful than placebo/standard therapy. These two studies were the main sources of  
242 heterogeneity in our analysis, although removing those studies from the tocilizumab subgroup  
243 did not change the direction of effect and statistical significance (RR=1.00 (95%CI 0.80-  
244 1.24),  $I^2=0\%$ , fixed-effects). Publication bias was indicated in the anti-spike-protein  
245 subgroup. The trim-and-fill method altered neither the direction of effect nor the statistical  
246 significance (RR=0.92 (95%CI 0.63-1.36),  $I^2=27\%$ , fixed-effects).

247

## 248 **DISCUSSION**

249 Our analyses showed that monoclonal antibodies provided benefits on mortality rate  
250 reduction, mostly because of the weight of tocilizumab studies. From subgroup analysis,  
251 tocilizumab showed this benefit, while sarilumab did not. Analysis of the need for  
252 mechanical ventilation was conducted by employing only anti-IL-6R studies since the others  
253 did not report this outcome. Additionally, some RCTs were outpatients and in mild-moderate  
254 disease. No significant benefit was found on hospital discharge at day 28-30 from pooling all

255 monoclonal antibodies. However, subgroup analysis demonstrated that tocilizumab had a  
256 significantly higher hospital discharge rate, but sarilumab and bamlanivimab did not. Most of  
257 the publications included in this study did not specify any specific description about the  
258 hospital discharge. We obtained this data from the description of their ordinal severity scale.  
259 In addition, the symptom progression score was not compared because it was described  
260 differently across studies.

261 Next, we also performed a meta-analysis assessing the efficacy of monoclonal  
262 antibodies in lowering viral load. For this particular purpose, all included studies employed  
263 anti spike-proteins (Chen et al., 2021; Gottlieb et al., 2021; Weinreich et al., 2021). There  
264 were three studied interventions—bamlanivimab, bamlanivimab-etesevimab, and REGN-  
265 COV2. As the results, the pooled effect of bamlanivimab studies did not show significant  
266 viral load reduction. Meanwhile, bamlanivimab-etesevimab and REGN-COV2 reported  
267 significant viral load reduction, but each was evaluated only from one RCT, therefore we  
268 cannot evaluate the pooled effect. Finally, safety profile should be taken into consideration  
269 when administering monoclonal antibodies in COVID-19 patients. Our analyses showed that  
270 monoclonal antibodies did not show significant harm or benefit as compared to  
271 placebo/standard care. However, not all studies included in this meta-analysis specified the  
272 number of treatment-related severe adverse events. The researchers considerably assumed  
273 that severe adverse events were related to the treatment unless it was specified otherwise.

274 We believe that pooling different monoclonal antibodies into one outcome analysis is  
275 not insightful since different interventions should be treated independently as they could  
276 display varying results. Therefore, we also aimed to look into the subgroup analysis in  
277 addition to the overall effect of the pooled antibodies.

## 278 **ANTI-IL-6R**

279 The efficacy of tocilizumab was mostly reported in studies where the participants received  
280 corticosteroids, for example in RECOVERY and REMAP-CAP trials. If these studies were  
281 excluded from the analysis, the pooled effect of mortality risk reduction was no longer  
282 significant. This highlights the potential benefit of the combination of tocilizumab and  
283 corticosteroids in mortality risk reduction. Indeed, it was shown that dexamethasone  
284 significantly reduced mortality risk (Sterne et al, 2020). This could also indicate that the  
285 tocilizumab effect may be additional to the corticosteroid benefit (Horby et al, 2021).  
286 Whether the administration of tocilizumab alone, without another immunomodulatory agent,

287 would reduce mortality risk remains unclear. Therefore, it is recommended that the use of  
288 tocilizumab in severe-critical COVID-19 patients is combined with corticosteroids rather than  
289 tocilizumab alone.

290 Next, our subgroup analysis showed that tocilizumab was beneficial in reducing mechanical  
291 ventilation needs and hospital discharge. Consistently, the benefits of tocilizumab in  
292 improving oxygen-support and mechanical ventilation rate have been previously documented  
293 (Aziz et al., 2021; Kotak et al., 2020; Tleyjeh et al., 2021). Additionally, REMAP-CAP and  
294 EMPACTA trials reported that the administration of tocilizumab was associated with earlier  
295 hospital discharge and reduction of hospital stay, respectively.

296 We failed to demonstrate the benefit of sarilumab in reducing the need for mechanical  
297 ventilation and hospital discharge rate. This was in line with another study (Della-Torre et al.,  
298 2020). The following are some of the proposed arguments to explain this finding. First, the  
299 open-label REMAP-CAP trial showed that the sample size included in the sarilumab group  
300 was smaller than the control group. Second, the double-blind EudraCT trial reported that  
301 more than 60% of patients in the trial received systemic corticosteroids before, during, or  
302 after infusion of the studied drug and the frequency of systemic corticosteroid varied during  
303 the study. Consequently, it might have diminished the differences between the investigational  
304 drug and the control group.

305 Anti IL-6R was generally safe and tolerable for the treatment of COVID-19 patients. A  
306 previous study reported no significant differences between tocilizumab and control groups in  
307 terms of the risk of treatment-related serious adverse events (Lin et al, 2021). Tocilizumab,  
308 moreover, had a lower rate of serious infections compared to those in the control group  
309 (Kotak et al, 2020; Lan et al., 2020; Zhao et al., 2021).

310 Lastly, the SARS-CoV-2 infection may result in excessive release of pro-inflammatory  
311 cytokines, including IL-6, an important cytokine associated with disease severity and  
312 mortality, which leads to hyperactivation of the immune response associated with acute  
313 respiratory distress syndrome (Xu et al., 2020). However, although IL-6 is one of major  
314 cytokines that drive CRS, IL-6 suppression alone might be insufficient to cease the  
315 hyperinflammatory phase of COVID-19. Moreover, although there was an increased IL-6  
316 level in COVID-19 patients, it was not as high as observed in sepsis or ARDS (Leisman et  
317 al., 2020; Sinha et al., 2020). In general, healthcare providers need to consider patients with  
318 severe COVID-19 to attain the maximum benefit from the inhibition of IL-6.

319 **ANTI-SPIKE-PROTEIN**

320 Viral load reduction of bamlanivimab was evaluated by two studies (Chen et al., 2021;  
321 Gottlieb et al., 2021) from the same RCT, BLAZE-1 (NCT04427501). Both studies reported  
322 that bamlanivimab 700mg and bamlanivimab 7000mg did not reduce viral load at day 11.  
323 Gottlieb et al. (2021) reported that only bamlanivimab 2800mg showed a higher viral load  
324 reduction although it was statistically insignificant, while Chen et al. (2020) reported that  
325 bamlanivimab 2800mg significantly reduced viral load.

326 Prozone-like effect possibly plays a role for the reduced efficacy at higher dose, more likely  
327 in the earlier time of the disease (Vaidya et al., 2017; Casadevall et al., 2021). Besides, the  
328 natural course of the disease also plays a role in viral load reduction. This may mask the  
329 clinical significance of neutralizing antibody administration. It is important to mention that  
330 missing data from Gottlieb et al. (2020) was replaced using an approach detailed in  
331 *Supplementary Materials*.

332 Among these anti-spike-protein antibodies, REGN-COV2 and bamlanivimab-etesevimab  
333 showed statistically significant viral load reduction but bamlanivimab alone did not reduce  
334 viral load. This finding was in line with FDA's decision published on 16 April 2021 stating  
335 that FDA revoked its previously issued EUA for monoclonal antibody bamlanivimab (FDA,  
336 2021). There is a possibility that etesevimab has superior efficacy on viral load reduction.  
337 Another possibility is that etesevimab and bamlanivimab may have synergistic effects.  
338 However, further research on clinical efficacy of etesevimab monotherapy and its  
339 pharmacokinetics with bamlanivimab are warranted.

340 Finally, it is important to note that BLAZE-1, ACTIV-3 and REGN-COV2 research were  
341 sponsored by the same company that designed the drug. Moreover, although all serious  
342 adverse events were reported, only some were judged by investigators to be treatment related.  
343 However, these studies are double-blinded. To correct the publication bias, trim-and-fill  
344 method was performed and the result remained similar.

345 **ANTI-C5a**

346 At present, there was only one study investigating anti-C5a with two outcomes included in  
347 this meta-analysis: the all-cause mortality and safety profile of the monoclonal antibody  
348 therapy. The mortality rate in anti-C5a antibody IFX-1 (vilobelimab) group vs. placebo was  
349 numerically lower, 13.3% vs 26.7%, respectively. However, this finding did not reach

350 statistical significance, probably owing to the small number of participants. Additionally,  
351 compared to placebo/standard care, neither benefit nor harm was observed.

352

### 353 **LIMITATION**

354 This meta-analysis has several limitations: (1) some studies were open-labelled; thus, the risk  
355 of bias regarding allocation concealment in those studies could not be ruled out; (2) We  
356 mainly discussed IL-6R inhibitors (e.g., tocilizumab) because most published RCTs are  
357 tocilizumab-associated studies and existing studies on other antibodies are scarce. (3) The  
358 small number of participants in some studies may increase the likelihood of type II statistical  
359 error. Larger scale RCTs are required to confirm the findings; (4) many other trials are  
360 ongoing; therefore, this study needs to be updated as soon as more trials become available.  
361 Nevertheless, this meta-analysis provides a solid evidence by incorporating only RCTs. To  
362 the best of our knowledge, this is the first meta-analysis that investigated the efficacy and  
363 safety of various monoclonal antibodies on clinical and laboratory outcomes, as well as their  
364 safety profile in patients with COVID-19.

365

### 366 **CONCLUSION**

367 In conclusion, monoclonal antibody is beneficial in reducing mortality risk and the need for  
368 mechanical ventilation, but not hospital discharge in COVID-19 patients. In contrast to  
369 sarilumab, tocilizumab reduces mortality risk in severe to critical patients, reduces the need  
370 for mechanical ventilation, and increases hospital discharge at day 28-30. Bamlanivimab  
371 monotherapy does not reduce mortality, increase hospital discharge, nor reduce viral load;  
372 while bamlanivimab-etesevimab and REGN-COV2 significantly decrease viral load. IFX-1  
373 shows no benefit in mortality risk reduction. No major safety concern was documented for all  
374 the monoclonal antibodies.

375

### 376 **Conflict of interest**

377 None declared.

378

### 379 **Ethical approval**

380 Not applicable.

381 **Funding**

382 None.
