Abstract

As vaccination against COVID-19 stalls in some countries, increased accessibility and more adaptive approaches may be useful to keep the epidemic under control. Here, we study the impact of reactive vaccination targeting schools and workplaces where cases are detected, with an agent-based model accounting for COVID-19 natural history, vaccine characteristics, individuals' demography and behaviour and social distancing. At an equal number of doses reactive vaccination produces a higher reduction in cases compared with non-reactive strategies, in the majority of scenarios. However, at high initial vaccination coverage or low incidence, few people are found to vaccinate around cases, thus the reactive strategy may be less effective than non-reactive strategies with moderate/high vaccination pace. In case of flare-ups, reactive vaccination could hinder spread if it is implemented quickly, is supported by enhanced test-trace-isolate and triggers an increased vaccine uptake. These results provide key information to plan an adaptive vaccination deployment.

Introduction

Vaccination against SARS-CoV-2 has changed the course of the COVID-19 pandemic thanks...
to the high effectiveness of available vaccines in preventing infection and severe forms of the
disease. Still, several months into the vaccination campaign vaccine uptake remains below
official targets in many Western countries due to logistical issues, vaccine accessibility and/or
hesitancy. As of Fall 2021, less than 60% of the population in the United States and Europe
was fully vaccinated. With intense virus circulation still ongoing in many regions of the world
due to the Delta variant and the threat posed by emerging variants, it is important to
investigate if vaccine use could improve with adaptive delivery. Indeed, proposing vaccination
to individuals who were exposed to the virus allows targeting those at higher risk of infection
and, furthermore, might help overcome barriers to vaccination since vaccine-hesitant
people are more likely to accept vaccination when the perceived risk of infection is higher.

Redirecting vaccine supplies to geographic areas of highest incidence (or hotspot
vaccination) is already part of some European countries’ plans and was implemented to
combat the emergence of variant Delta. But other reactive vaccination schemes are
possible, such as ring vaccination that targets contacts of confirmed cases or contacts of
those contacts, or vaccination in workplaces or schools where cases have been detected.
This could potentially improve vaccine impact by preventing transmission where it is active
and even enable the efficient management of flare-ups. For outbreaks of smallpox or Ebola
fever, ring vaccination has proved effective to rapidly curtail the spread of cases. However,
the experience of these past epidemics cannot be transposed directly to COVID-19 due to the
many differences in the infection characteristics and epidemiological context. For example,
COVID-19 cases are infectious a few days before symptom onset, but generally detected a
few days later. This means they may have had time to infect their direct contacts, preventing
the effectiveness of ring vaccination to prevent secondary cases. Vaccinating an extended
network of contacts, as could be done with the vaccination of whole workplaces or schools,
would have a larger impact, especially if adopted in combination with strengthened protective
measures to slow down transmission, such as masks, physical distancing, and contact
tracing. This could be feasible in many countries, leveraging the established test-trace-isolate
(TTI) system that enables prompt detection of clusters of cases to inform where vaccines
should be deployed. Properly assessing the interest of reactive vaccination therefore requires
to consider in detail the interactions of vaccine characteristics, pace of vaccination, COVID-19
natural history, case detection practices and overall changes in human contact behaviour.

We therefore extend an agent-based model that has been previously described to quantify
the impact of a reactive vaccination strategy targeting workplaces, universities and 12+ years
old in schools where cases have been detected. We compare the impact of reactive
vaccination with non-reactive vaccination targeting similar settings or with mass vaccination,
and test these strategies alone and in combination. We explore differences in vaccine
availability and logistic constraints, and assess the influence of the dynamic of the epidemic
and different stages of the vaccination campaign.

Results

Mass vaccination, targeted, and reactive vaccination strategies

We extend a previously described SARS-CoV-2 transmission model \(^\text{10}\) to simulate vaccine administration, running in parallel with other interventions - i.e. contact tracing, teleworking and social restrictions. Following similar approaches \(^\text{11–14}\), the model is stochastic and individual based. It takes as input a synthetic population reproducing demographic, social-contact information, workplace sizes and school types (Figure 1A) of a typical medium-sized French town (117,492 inhabitants). Contacts are described as a dynamic multi-layer network \(^\text{10}\) (Figure 1B).

We assume that the vaccine reduced susceptibility, quantified by the vaccine effectiveness \(V E_s\), and symptomatic illness after infection, quantified by \(V E_{sp}\) \(^\text{15}\) (Figure 1C). We consider a vaccination strategy based on the Cominarty vaccine \(^\text{16}\) which is very suitable for reactive vaccination as it is effective, requires only three weeks between the two doses conferring protection and is available in large quantities. We describe the vaccine-induced protection accounting for the vaccine characteristics against the Delta variant - i.e. the dominant variant at the time of writing. Real-life estimates differ, reflecting the complex interplay among the timing of Delta introduction in the population, the co-circulation of other variants, waning of immunity and differential impact by age. In the baseline analysis we consider vaccine effectiveness levels in the middle of the range of estimates provided in a systematic review \(^\text{17}\).

We used a three-week interval between doses as in the vaccine trial. \(^\text{16}\) For vaccine protection, we conservatively assume that there was no protection in the 2 weeks after the first inoculation, followed by intermediate protection until 2 weeks after the second dose \(V E_{s,1}=48\%\) and \(V E_{sp,1}=53\%\), see additional details in Table S2 of the Supplementary Information and maximum protection from this date on \(V E_{s,2}=70\%\) and \(V E_{sp,2}=73\%\), 5 weeks after the first dose. The maximum protection values are close to the estimates obtained in a meta-analysis for Delta, all vaccines combined \(^\text{18}\). Lower and higher vaccine effectiveness are also explored.
Figure 1. **A** Distribution of workplace size and of school type for the municipality of Metz (Grand Est region, France), used in the simulation study. **B** Schematic representation of the population structure, the reactive vaccination and contact tracing. The synthetic population is represented as a dynamic multi-layer network, where layers encode contacts in household, workplace, school, community and transport. In the figure, school and workplace layers are collapsed and community and transport are not displayed for the sake of visualisation. Nodes repeatedly appear on both the household and the workplace/school layer. The identification of an infectious individual (in purple in the figure) triggers the detection and isolation of his/her contacts (nodes with orange border) and the vaccination of individuals attending the same workplace/school and belonging to the same household who accept to be vaccinated (green). **C** Compartmental model of COVID-19 transmission and vaccination. Description of the compartments is reported on the Methods section. **D** Timeline of events following infection for a case that is detected in a scenario with reactive vaccination. For panels C, D transition rate parameters and their values are described in the Methods and in the Supplementary Information.

To parametrise the epidemiological context we assume 32%\textsuperscript{19,20} of the population was fully immune to the virus due to previous infection and the reproductive ratio is $R = 1.6$, in the range of values estimated for the Delta wave of summer 2021\textsuperscript{1,21}. We model the baseline TTI policy after the French situation, allowing 3.6 days on average from symptoms onset to detection and 2.8 average contacts detected and isolated per index case\textsuperscript{22} (Figure 1 D). We assume that 50% of clinical cases and 10% of subclinical cases are detected, leading to an
The overall detection rate is approximately 25%. Scenarios with enhanced TTI are described later in the text.

We then model vaccination targeting all adults older than 12 years old with baseline vaccine uptake - set to 80% in the 12-65 years old and 90% in the over 65 years old. We assumed that priority risk groups (e.g. elderlies) had already been vaccinated up to that level at the start. We model three non-reactive vaccination strategies in the general population, where vaccination is deployed i) randomly throughout the mass vaccination program (mass) or ii) in schools sites (school location, described below) or iii) in workplaces/universities (workplaces/universities) chosen at random, up to the maximum number of doses available daily. In the school location vaccination, we assume vaccine sites are created in relation with schools to vaccinate pupils and their household members who are above 12 years old. Then, we model a reactive vaccination strategy, where the detection of a case thanks to TTI triggers the vaccination of household members and those in the same workplace or school (Figure 1D). In this scenario, a delay of 2 days on average is assumed between the detection of the case and starting vaccination to account for logistical issues - i.e. ~5.6 days on average from the index case's symptoms onset. In the context of reactive vaccination, we test scenarios with vaccine uptake set to its baseline values, and as high as 100%. The impact of each strategy is evaluated based on the comparison with a reference scenario, where no vaccination campaign is conducted during the course of the simulation and vaccination coverage remains at its initial level.

In Figure 2 A, B, C we compare all strategies, assuming that vaccine uptake is the same in reactive and non-reactive vaccination as reference, and initial vaccination coverage is low, i.e. ~30% over the population - with 15% of the [12,60] group and 90% of the 60+ group already vaccinated at the beginning. Similar low coverage values were registered in some countries in Eastern Europe and US counties during the Fall 2021. For non-reactive strategies, the vaccination pace is varied between 100 and 500 first doses per 100,000 inhabitants per day. Vaccination pace in Western countries roughly fell within these extremes for the majority of the vaccination campaign, with lower values in general reached around the beginning and the end, due to delivery issues at the beginning, and difficulty in overcoming barriers to vaccination at the end. For the reactive strategy, vaccine deployment is triggered by detected cases, therefore the number of doses used and the number of places where these doses are administered depends on the epidemic situation. We assume moderate/high initial incidence, i.e. ~160 clinical cases weekly per 100,000 inhabitants. Panel A shows the relative reduction in the attack rate after two months as a function of the number of first daily doses and Panel B compares the incidence profiles under different strategies with the same number of vaccine doses. The mass, school location and workplaces/universities strategies have a similar impact on the epidemic. They lead to a reduction between 2.7% and 3% of the attack.
rate with 100 first doses per 100,000 inhabitants administered each day, and between 13% and 15% with 500 per 100,000 inhabitants. The reactive vaccination produces a stronger reduction in cases than the three other strategies in the 2-months period (black dots in Figure 2 A and black line in Figure 2 B). We find that 417 doses per 100,000 inhabitants each day on average are used under the epidemic scenario considered here, yielding an attack-rate relative reduction of 20%.

In panel C we consider the same parametrization as in Figure A, B and we show the number of first doses in time and the number of places to vaccinate - as a proxy to the incurred logistics of vaccine deployment. The number of daily inoculated doses is initially high, with almost 1200 doses per 100,000 inhabitants used in a day at the peak of vaccine demand, but declines rapidly afterwards down to 6 doses. The number of workplaces to vaccinate follows a different trend. It slowly increases to reach a peak and then declines. The breakdown in Figure S3 of the Supplementary Information shows that schools and large workplaces are vaccinated at the very beginning. Thus a great number of vaccines are initially deployed in large settings, requiring many doses, while as the epidemic spreads it reaches a large number of small settings where only a few individuals can be vaccinated.
Figure 2. A, D, G Relative reduction (RR) in the attack rate (AR) over the first two months for all strategies as a function of the vaccination pace. RR is computed as \( \frac{AR_{ref} - AR}{AR_{ref}} \) where \( AR_{ref} \) is the AR of the reference scenario, where no vaccination campaign is conducted during the course of the simulation and vaccination coverage remains at its initial level. AR is computed from clinical cases. Three initial vaccination coverage are investigated for adults: 15\%, i.e. low vacc. cov. (A); 40\%, i.e. intermediate vacc. cov. (D) and 65\%, i.e. high vacc. cov. (G).

B, E, H Incidence of clinical cases with different vaccination strategies. The non-reactive scenarios plotted are obtained with the same daily vaccination pace than for reactive vaccination. Low, intermediate and high vaccination coverages are investigated for adults in panels B, E, H, respectively.

C Number of daily first-dose vaccinations, and number of workplaces/schools (WP/S in the plot) where vaccines are deployed for the same reactive scenario as in A, B - low vacc. cov., with 15\% initial vaccine coverage. For the other vaccination coverages the curves are qualitatively similar (results not shown). F AR RR for different initial vaccination coverage of adults. The four strategies are compared at equal numbers of vaccine doses. The size of the points is proportional to the average daily vaccination pace. I: AR RR for different Vaccine effectiveness levels (VE). The baseline VE values used in the other panels is compared with a worst and a best scenario. The worst scenario is defined by \( V_{E,S,1} = 30\% \), \( V_{E,SP,1} = 35\% \), \( V_{E,S,2} = 53\% \) and \( V_{E,SP,2} = 60\% \), while the best scenario is defined by \( V_{E,S,1} = 65\% \), \( V_{E,SP,1} = 75\% \), \( V_{E,S,2} = 80\% \) and \( V_{E,SP,2} = 95\% \). For each VE level the four
strategies are compared at equal number of vaccine doses. In panel I we consider the intermediate vaccination coverage - i.e. 40% initial coverage among adults. In all panels we assumed the following parameters: R=1.6; Initial immunity 32%; vaccinated at the beginning 90% for 60+; 10% of individuals are doing teleworking and 5% of community contacts are removed. Values are means over 2000 stochastic simulations. Error bars in panels A, D, G, F, I are derived from the standard errors of the AR. These are smaller than the size of the dots in almost all cases. Shaded areas in panels B, C, E, H indicate the standard errors - very low in panels B, E, H.

In panels D, E we consider an intermediate vaccination coverage at the beginning (40% of the [12,60] group and 90% of 60+, corresponding to ~45% of the whole population). Non-reactive strategies lead to a relative reduction in the attack rate after two months close to the low initial coverage case. Instead, the impact of reactive vaccination is reduced. A smaller proportion of people attending workplaces/schools that are targeted by vaccination are left to vaccinate, therefore less vaccines are deployed with reduced impact on the epidemic at the population level (Figure 2 D). Still, with ~250 doses per 100,000 inhabitants each day used on average, reactive vaccination produced a 13% reduction in the attack rate. This value is close to the reduction level reached with non-reactive strategies with 400 doses per 100,000 inhabitants each day. The impact of reactive vaccination becomes very small when initial vaccination coverage is high. Panels G, H show a scenario where 65% of the [12,60] group and 90% of 60+ is vaccinated at the beginning, corresponding to ~60% of the whole population close to the coverage reached in Europe in the Fall 2021. Only 94 daily vaccines per 100000 inhabitants are deployed each day with a 5% reduction in the attack rate compared to the 2% reduction of non-reactive strategies at equal number of doses. Non-reactive strategies with vaccination pace higher or equal to 300 doses per 100,000 inhabitants each day produce a higher reduction in cases (~8% or higher).

The effect of the initial vaccination coverage on the impact of the different strategies is summarized in Figure 2 F. The relative reduction declines roughly linearly with the initial vaccination coverage. The reactive vaccination always outperforms non-reactive strategies at equal number of doses. Still, the number of vaccinated people in the reactive vaccination progressively decreases as initial vaccination coverage increases, to reach the point in which the strategy is less effective compared to non-reactive strategies with not-small vaccination pace. Eventually, in panel I we explore different levels of vaccine effectiveness encompassing the whole range of estimates provided by real life estimates. We find that lower vaccine effectiveness values lead to a reduced effect of vaccination as expected. The difference between reactive and non-reactive strategies is also reduced.

In the Supplementary Information we analyse the comparison between reactive and non-reactive strategies with varying key parameters. In Figure S4 we assumed the baseline scenario of Figure 2 D, E, i.e. intermediate vaccination coverage at the beginning - ~45% of the whole population vaccinated. We explore alternative values of transmission, incubation period, immunity level of the population, reduction in contacts due to social distancing, time...
needed for the vaccine to become effective, compliance to vaccination and vaccine effect on the infection duration. Increase in the reproductive ratio, initial immunity and time between doses reduce the impact of the reactive vaccination. An increase in compliance to vaccination, instead, enhanced the impact of both reactive and non-reactive vaccination. Other parameters had a more limited role on strategies' effectiveness. We then consider a scenario of a flare-up of cases, as it may be caused by a new variant of concern (VOC) spreading in the territory (Figure S5). The deployment of vaccines is in this case limited and slow. Depending on the values of the other parameters, i.e. proportion of teleworking and time from building immunity following vaccination, the reactive strategy may bring limited or no benefit with respect to non-reactive strategies, when the comparison is done at equal number of doses. Eventually, we test the robustness of our results according to the selected health outcome, using hospitalisations, ICU admissions, ICU bed occupancy, deaths, life-years lost and quality-adjusted life-years lost, finding the same qualitative behavior.

Combined reactive and mass vaccination for managing sustained COVID-19 spread

With high availability of vaccine doses, reactive vaccination could be deployed on top of mass vaccination. We consider the intermediate vaccination coverage scenario (i.e. ~45% of the whole population vaccinated) defined in the previous section and compare mass and reactive vaccination simultaneously (combined strategy) with mass vaccination alone. We focus on the first two months since the implementation of the vaccination strategy. At an equal number of doses within the period, the combined strategy outperforms mass vaccination in reducing the attack rate. For instance, the relative reduction in the attack rate would go from 10%, when ~360 daily doses per 100,000 inhabitants are deployed for mass vaccination, to 16%, when the same number of doses are used for reactive and mass vaccination combined (Figure 3A).

We explore alternative scenarios where the number of vaccines used and places vaccinated are limited due to availability and logistic constraints. We assess the effect of three parameters: (i) the maximum daily number of vaccines that can be allocated towards reactive vaccination (with caps going from 50 to 250 per 100,000 inhabitants, compared with unlimited vaccine availability assumed in the baseline scenario), (ii) the time from the detection of a case and the vaccine deployment (set to 2 days in the baseline scenario, and here explored between 1 and 4 days), and (iii) the number of detected cases that triggers vaccination in a place (from 2 to 5 cases, vs. the baseline value of 1). The number of first-dose vaccinations in time under the different caps is plotted in Figure 3 B. A small cap on the number of doses limits the impact of the reactive strategy. Figure 3 C shows that the attack rate relative reduction drops from 16% to 6% if only a maximum of 50 first doses per 100,000 inhabitants daily can be used in reactive vaccination, reaching the levels of mass vaccination only.
Doubling the time required to start reactive vaccination, from 2 days to 4 days, has a limited effect on the reduction of the AR (relative reduction reduced from 16% to 15%, Figure 3D). Increasing the number of detected cases used to trigger vaccination to 2 (respectively 5) reduces the relative reduction to 11% (respectively 6%) (Figure 3E). We so far assumed that vaccine uptake is the same in mass and reactive vaccination. This assumption is likely conservative, in that individuals may be more inclined to accept vaccination when this is proposed in the context of reactive vaccination due to the higher perceived benefit of vaccination. In Figure 3F we consider a scenario where vaccine uptake with reactive vaccination climbs to 100%. Attack rate relative reduction increases in this case from 16% to 22%, with a demand of ~480 daily doses per 100,000 inhabitants on average.

Figure 3. A Relative reduction (RR) in the attack rate (AR) over the first two months for the combined strategy (mass / reactive) and the mass strategy with the same number of first-dose vaccinations as in the combined strategy during the period. RR is computed with respect to the reference scenario with initial vaccination only, as in Figure 2. Combined strategy is obtained by running in parallel the mass strategy - from 50 to 250 daily vaccination rate per 100,000 inhabitants - and the reactive strategy. Number of doses displayed in the x-axis of the figure is the total number of doses used by the combined strategy daily. Corresponding incidence curves are reported in Figure S7 of the Supplementary Information. B Number of first-dose vaccinations deployed each day for the combined strategy with different daily vaccines’ capacity limits. C, D, E AR RR for the combined strategy as a function of the average daily number of first-dose vaccinations in the two-month period. Symbols of different colours indicate: (C) different values of daily vaccines’ capacity limit; (D) different time from case detection to vaccine deployment; (E) different threshold size for the cluster to trigger vaccination. In panel C and E the curve corresponding to mass vaccination only is also plotted for comparison. F Comparison between 100% and baseline vaccination uptake in case of reactive vaccination. In all cases we assumed the following parameters: R=1.6; Initial
immunity 32%; vaccinated at the beginning 90% and 40% for 60+ and <60, respectively; 10% of individuals are doing teleworking and 5% of community contacts are removed. Values are means over 2000 stochastic simulations, error bars are derived from the standard errors of the AR. In panel B only the standard error of the unlimited case is shown, this indicated by the shaded area.

Combined reactive and mass vaccination for managing a COVID-19 flare-up

We have previously said that in a scenario of flare-up of cases reactive vaccination would bring limited benefit compared to other strategies (Figure S5 of the Supplementary Information). Here we analyse this scenario more in depth, assuming that reactive vaccination is combined with mass vaccination, but triggers an increase in vaccine uptake and is associated with enhanced TTI, as may be the case in a realistic scenario of alert due to initial VOC detection.

We assume mass vaccination with 150 first doses per day per 100,000 inhabitants is underway from the start, with intermediate vaccination coverage at the beginning (i.e. ~45% of the whole population vaccinated). We assume baseline TTI is in place prior to cases’ introduction. To start a simulation, three infectious individuals carrying a VOC are introduced in the population where the virus variant is not currently circulating. Upon detection of the first case, we assume that TTI is enhanced, finding 70% of clinical cases, 30% of subclinical cases (i.e. ~45% of all cases) and three times more contacts outside the household with 100% compliance to isolation (Table S4 of the Supplementary Information) - the scenario without TTI enhancement is also explored for comparison. As soon as the number of detected cases reaches a predefined threshold, reactive vaccination is started on top of the mass vaccination campaign. We assume vaccine uptake increases to 100% for reactive vaccination but stays at its baseline value for other approaches.

In Figure 4 we compare the combined scenario with mass vaccination alone at an equal number of doses, and we investigate starting the reactive vaccination after 1, 5 or 10 detected cases. Panels A, B show the case of baseline transmissibility and vaccine effectiveness. With reactive vaccination starting from the first detected case, the attack rate decreases by ~10%, compared with the mass scenario. However, the added value of reactive vaccination decreases if more detected cases are required to start the intervention. Without enhancement in TTI and increase in vaccine uptake, attack rate values are much higher and the benefit of reactive vaccination over the mass vaccination is lower (~3%).

In the Supplementary Information we consider different epidemic scenarios, testing different values for the transmissibility and vaccine effectiveness - including worst-case vaccine effectiveness, and R as high as 1.8 -, finding similar trends. Eventually, we analysed the impact of vaccination on the flare-up extinction. With the parameterization of Figure 4 A we find probabilities of extinction equal to ~5.5% and ~6% with mass and combined strategies,
respectively. These values respectively become \(~15\%\) and \(~18\%\) in a best-case scenario with a more rapid mounting of vaccine effect after the first dose, best-case vaccine effectiveness and strong TTI.

Figure 4 A, B Average attack rate per 100000 inhabitants in the first two months for the enhanced (A) and baseline (B) TTI scenario. Four vaccination strategies are compared: mass only, combined where the reactive vaccination starts at the detection of 1, 5, 10 cases (Comb. cl. s. = 1, 5, 10 in the figure). For mass vaccination the number of first-dose vaccinations during the period is the same as in the comb. cl. s=1 of the same scenario. In all panels we assume the following parameters: \(R=1.6\); initial immunity 32\%; 90\% for 60+ year old and 40\% for <60 years old already vaccinated at the beginning; 10\% of individuals are doing teleworking and 5\% of community contacts are removed. Corresponding incidence curves are reported in Figure S8 of the Supplementary Information. Error bars are the standard errors from 8000 stochastic realisations.

**Discussion**

The rapid rise of new SARS-CoV-2 variants with increased transmissibility has made the course of the COVID-19 pandemic unpredictable, posing a persistent public health threat that jeopardises relaxation of NPIs and return to normal life\(^{25,30–34}\). More transmissible viruses call for vaccination of a larger proportion of the population, therefore vaccination must be made more accessible and able to adapt to a rapidly evolving epidemic situation\(^2\). In this context, we have analysed the reactive vaccination of workplaces, universities and schools to assess its potential role in managing the epidemic.

We presented an agent-based model that accounts for the key factors affecting the effectiveness of reactive vaccination: disease natural history, vaccine characteristic, individual contact behaviour, and logistic constraints. For a wide range of epidemic scenarios, the reactive vaccination had a stronger impact on the COVID-19 epidemic compared to non-reactive vaccination strategies (including the standard mass vaccination) at equal number of doses used within the two months after inception. In addition, combining reactive and mass vaccination was more effective than mass vaccination alone. For instance, in a scenario of moderate/high incidence with \(~45\%\) vaccination coverage at the beginning we found that the
relative reduction in the attack rate after two months would improve from 10% to 16% with
~350 daily first vaccine doses per 100000 habitants used in a combined mass/reactive
vaccination approach instead of mass only. However, reactive vaccination had limited or no
advantage with respect to non-reactive strategies under certain circumstances, as the number
of doses administered with the reactive vaccination depended on the number and pace of
occurrence and detection of COVID-19 cases. This may be the case when vaccination
coverage is already high at the beginning and only a few people to vaccinate are found
around detected cases, or in a flare-up scenario when only a few cases are detected. Non-
reactive strategies could then be more effective as long as the pace of vaccine administration
is not small. Yet, in these situations, adding reactive vaccination to mass vaccination could
become of interest again by triggering an increase in vaccine uptake, all the more if this is
combined with enhanced TTI.

Reactive vaccination has been studied for smallpox, cholera and measles, among others 5–
7,35,36. Hotspot vaccination was found to help in cholera outbreak response by both modelling
studies and outbreak investigation 36,37. It may target geographic areas defined at spatial
resolution as diverse as districts within a country, or neighbourhoods within a city, according
to the situation. For Ebola and smallpox ring vaccination was successfully adopted to
accelerate epidemic containment 5–7. For these infections, vaccine-induced immunity mounts
rapidly compared to the incubation period and contacts of an index case can be found before
they start transmitting since pre-symptomatic and asymptomatic transmission is almost
absent. Ring vaccination is also likely effective when the vaccine has post-exposure effects 8.
Reactive vaccination of schools and university campuses has been implemented in the past
to contain outbreaks of meningitis 38 and measles 39,40.

For COVID-19, the use of reactive vaccination has been reported in Ontario, the UK,
Germany, France, among others 2,41–46. In these places, vaccines were directed to
communities, neighbourhoods or building complexes with a large number of infections or
presenting epidemic clusters or surge of cases due to virus variants. The goal of these
campaigns was to minimise the spread of the virus, but it also addressed inequalities in
access and increased fairness, since a surge of cases may happen where people have
difficulty in isolating due to poverty and house crowding 47. In France, reactive vaccination
was implemented to contain the emergence of variants of concerns in the municipalities of
Bordeaux, Strasbourg and Brest 44–46. In the municipality of Strasbourg, vaccination slots
dedicated to students were created following the identification of a Delta cluster in an art
school 44. Despite the interest in the strategy and its inclusion in the COVID-19 response
plans, very limited work has been done so far to quantify its effectiveness 48,49. A modelling
study on ring-vaccination suggested that the strategy could be valuable if the vaccine has
post-exposure efficacy and a large proportion of contacts could be identified 49. Still, post-
exposure effects of the vaccine remain currently under-investigated, and it is likely that the vaccination of the first ring of contacts alone would bring little benefit, if at all. We have here tested reactive vaccination of workplaces and schools, since focusing on these settings may be an efficient way to easily reach an extended group of contacts. Workplaces have been found to be an important setting for COVID-19 transmission, especially specific workplaces where conditions are more favourable for spreading. University settings also cover a central role in the COVID-19 transmission, due to the higher number of contacts among students, particularly if sharing common spaces in residence accommodations. Model results show that reactive vaccination of these settings could have in many circumstances a stronger impact than simply reinforcing vaccination as in hotspot strategies.

However, the effectiveness of the reactive strategy depends on the epidemic context. We found that, as vaccination coverage increases, the relative advantage of reactive vaccination over non-reactive strategies diminishes. For >40% vaccination coverage among adults, the relative reduction of the strategy is smaller than the one produced by non-reactive vaccination at a moderate/high vaccination pace, under the hypothesis of no increase in vaccine uptake in the context of reactive vaccination. As discussed before, when a cluster is identified in a given workplace/school the vaccine is proposed only to a few individuals not previously vaccinated and compliant to vaccination, resulting in a limited deployment of vaccine and a reduced impact. In addition, breakthrough infection becomes an important driver of propagation when a large proportion of individuals are vaccinated, with consequently a larger proportion of subclinical cases and in turn a reduced detection rate overall. This makes the detection of outbreaks and consequently the reactive deployment of vaccines more difficult.

If initial vaccination coverage is not too high, the feasibility and advantage of the inclusion of reactive vaccination imply a trade-off between epidemic intensity and logistic constraints. At a moderate/high incidence level, combining reactive and mass vaccination would substantially decrease the attack rate compared to mass vaccination for the same number of doses, but the large initial demand in vaccines may exceed the available stockpiles. Even with large enough stockpiles, issues like the timely deployment of additional personnel in mobile vaccine units and the need to quickly inform the population by communication campaigns must be solved to guarantee the success of the campaign. We explored with the model the key variables that would impact the strategy effectiveness. Delaying the deployment of vaccines in workplaces/schools upon the detection of a case (from 2 to 4 days on average) would not have a strong impact on its effectiveness. However, vaccines should be deployed at the detection of the first case to avoid substantially limiting the impact of the strategy - e.g. the relative reduction goes from 16% to 6% when workplaces/schools are vaccinated at the detection of 5 cases (Figure 3E).

In the case of a COVID-19 flare-up the reactive strategy may bring an advantage if the
reactive strategy starts early, it is combined with increased TTI and it triggers an increase in vaccine uptake. First, an early start of the reactive vaccination campaign since the detection of the first VOC case requires that tests for the detection of variants must be carried out quickly and with large coverage. Genomic surveillance has ramped up in many countries since the emergence of the Alpha variant in late 2020. In France, nationwide surveys are conducted every two weeks involving the full genome sequencing of randomly selected positive samples. Approximately 50% of positive tests are also routinely screened for key mutations to monitor the circulation of the main variants registered as VOC or VUI. While these volumes of screening may be regarded as sufficient to quickly identify the presence of variants, the quick rising of large clusters of cases is possible, notably due to super spreading events, becoming increasingly frequent as social restrictions relax. Second, reactive vaccination must be part of a wider response plan, including notably a strong intensification of TTI. Rapid and efficient TTI efficiently mitigates spread on its own, but it is also instrumental to the success of reactive vaccination as it allows triggering vaccination in households, workplaces and schools. Third, an increased level of vaccine uptake is essential for reactive vaccination to be of interest. In many Western countries, upward trends in vaccine uptake have been observed as the vaccination campaign unfolds, thanks to government mandates, incentives by public health authorities, the communication effort and the strong evidence regarding vaccine efficacy. Still vaccination coverage is highly heterogeneous and remains low, e.g., in many countries of Eastern Europe and in many counties in the US. Besides the individuals who oppose vaccination, a reactive strategy may have the potential to increase acceptability of the vaccine by making it more accessible and anticipating an immediate benefit against the risk of infection. An increase in vaccine uptake was indeed observed in the context of a reactive vaccination campaign during the course of a measles outbreak. Therefore reactive vaccination could be an important way to improve access to vaccination - especially for the hard-to-reach population - and potentially increase acceptability, e.g. due to risk perception.

The study is affected by several limitations. First, the synthetic population used in the study accounts for the repartition of contacts across workplaces, schools, households, etc., informed by contact surveys. However, numbers of contacts and risk of transmission could vary greatly according to the kind of occupation. The synthetic population accounts for this variability assuming that the average number of contacts from one workplace to another is gamma distributed. Still, no data were available to inform the model in this respect. Second, we model vaccination uptake according to age only, when it is determined by several sociodemographic factors. Clusters of vaccine hesitant individuals may play an important role in the dynamics and facilitate the epidemic persistence in the population, as it is described for measles. In those countries where vaccination coverage is high, heterogeneities in attitude toward vaccination may have an impact. Third, the agent-based model is calibrated from...
French socio-demographic data. The results of this study can be extended to countries with similar societal structure and contact patterns, as e.g. other developed countries. Still, COVID-19 transmission potential, level of disease-induced immunity, vaccination coverage, and extent of social restrictions vary substantially from one country to another. In addition, the time since vaccination campaign was started, the consequent extent of waning of immunity and countries’ strategies of administering the vaccine booster affect the level of protection of the population already vaccinated and may alter the impact of reactive deployment of vaccines among individuals not yet vaccinated. We explored a large set of parameters in the Supplementary Information to provide fundamental understanding on the interplay between the epidemic and the reactive vaccination dynamics that may aid the planning of the strategy in case of future epidemic surges.

Methods

Synthetic population

We use a synthetic population for a French municipality based on the National Institute of Statistics and Economic Studies (INSEE) censuses and French contact survey information. This includes the following input files: i) a setting-specific, time-varying network of daily face-to-face contacts; ii) the maps between individuals and their age, iii) between individuals and the household they belong to, iv) between individuals and their school, v) and between individuals and their workplace. The synthetic population has age pyramid, household composition, number of workplaces by size, and number of schools by type, reproducing INSEE statistics. Daily face-to-face contacts among individuals are labelled according to the setting in which they occur (either household, workplace, school, community or transport) and they have assigned a daily frequency of activation, to explicitly model recurrent and sporadic contacts. We consider the municipality of Metz in the Grand Est region, which has 117,492 inhabitants, 131 schools (from kindergarten to University) and 2888 workplaces (Figure 1A). Detailed description of how the population was generated is provided in Information about how to access population files is provided in the Data availability section.

Overview of the model

The model is written in C/C++, and is stochastic and discrete-time. It accounts for the following components: (i) teleworking and social distancing, (ii) COVID-19 transmission, accounting for the effect of the vaccine; (iii) test-trace-isolate; (iv) vaccine deployment. Model output includes time series of incidence (clinical and subclinical cases), detailed information on infected cases (time of infection, age, vaccination status), vaccines administered according to the strategy, number of workplaces where vaccines are deployed. Different epidemic scenarios are explored and compared. In the Supplementary Information we also analyse...
hospitalisation entries, deaths, ICU entries, life-year lost, quality-adjusted life-year, ICU bed occupancy. These quantities are computed by postprocessing output files containing the detailed information on infected cases.

**Teleworking and social distancing**

Teleworking and other social restrictions may alter the repartition of contacts across settings and in turn the effectiveness of vaccination strategies. We thus explicitly accounted for this ingredient in the model. Specifically, to model teleworking we assume a proportion of nodes are absent from work, modelled by erasing working contacts and transport contacts of these nodes. To account for the reduction in social encounters due to the closure of restaurants and other leisure activities we removed a proportion of contacts from the community layer. In Western countries, level of restrictions varied greatly both by country and in time since vaccines were first deployed at the beginning of 2021. We set the contact reduction in the community to 5% and the teleworking to 10%. These are close to the reduction values reported by google mobility reports for France during Autumn 2021, and fall within the range of European countries’ estimates. Note that levels of teleworking ~10% for European countries are reported also by other sources. Scenarios with different levels of contact reduction are compared in the Supplementary Information. Telework and social distancing is implemented at the beginning of the simulation and remains constant for the duration of the simulation. Importantly, the reproductive ratio is set to the desired value, independently by the level of contact reduction, as described in the Supplementary Information.

**COVID-19 transmission model**

Transmission model is an extension of the model in (see Figure 1D). This accounts for heterogeneous susceptibility and severity across age groups, the presence of an exposed and a pre-symptomatic stage, and two different levels of infection outcome - subclinical, corresponding to asymptomatic infection and paucisymptomatic, and clinical, corresponding to moderate to critical infection. Precisely, susceptible individuals, if in contact with infectious ones, may get infected and enter the exposed compartment (E). After an average latency period they become infectious, developing a subclinical infection (I_sc) with age-dependent probability \( p_{sc} \) and a clinical infection (I_c) otherwise. From E, before entering either I_sc or I_c, individuals enter first a prodromal phase (either I_p,sc or I_p,c), that lasts on average \( \mu_p^{-1} \) days. Compared to I_p,c and I_c, individuals in the I_p,sc and I_sc compartments have reduced transmissibility rescaled by a factor \( \beta_I \). With rate \( \mu \) infected individuals become recovered. Age-dependent susceptibility and age-dependant probability of clinical symptoms are parametrised from. In addition, transmission depends on setting as in. We assume that the time spent in the E, I_p,sc and I_p,c compartments is Erlang distributed with shape 2, and rate 2 \( \epsilon \) for
We model vaccination with a leaky vaccine, partially reducing both the risk of infection (i.e. reduction in susceptibility, \( V E_S \)) and infection-confirmed symptomatic illness (\( V E_{SP} \)) \(^{15} \). Level of protection increases progressively after the inoculation of the first dose. In our model we did not explicitly account for the two-dose administration, but we accounted for two levels of protection – e.g. a first one approximately in between of the two doses and a second one after the second dose. Vaccine efficacy was zero immediately after inoculation, mounting then to an intermediate level (\( V E_{S,1} \) and \( V E_{SP,1} \)) and a maximum level later (\( V E_{S,2} \) and \( V E_{SP,2} \)).

This is represented through the compartmental model in Figure 1C. Upon administering the first dose, \( S \) individuals become, \( S^{V,0} \), i.e. individuals that are vaccinated, but have no vaccine protection. If they do not become infected, they enter the stage \( S^{V,1} \), where they are partially protected, then stage \( S^{V,2} \) where vaccine protection is maximum. Time spent in \( S^{V,0} \) and \( S^{V,1} \) is Erlang distributed with shape 2 and rate \( 2/\tau_0 \), and \( 2/\tau_1 \) for \( S^{V,0} \) and \( S^{V,1} \), respectively. \( S^{V,1} \) and \( S^{V,2} \) individuals have reduced probability of getting infected by a factor \( r_{S,1}=(1-V E_{S,1}) \) and \( r_{S,2}=(1-V E_{S,2}) \), respectively. In case of infection, \( S^{V,2} \) individuals progress first to exposed vaccinated (\( E^V \)), then to either preclinical or pre-subclinical vaccinated (\( I_{p,c}^V \) or \( I_{p,sc}^V \)) that are followed by clinical and subclinical vaccinated respectively (\( I^V \) or \( I^V_{sc} \)). Probability of becoming \( I_{p,c}^V \) from \( E^V \) is reduced of a factor \( r_{c,2}=(1-V E_{SP,2})(1-V E_{S,2})^{-1} \). For the \( S^{V,1} \) individuals that get infected we assume a polarised vaccine effect, i.e. they can enter either in \( E^V \), with probability \( p_V \), or in \( E \) (Figure 1D). The value of \( p_V \) can be set based on \( V E_{SP,1} \) through the relation \( (1-V E_{SP,1})= (1-V E_{S,1}) [p_V r_{c,2} + (1-p_V)] \). We assume no reduction in infectiousness for vaccinated individuals. However, we accounted for a 25% reduction in the duration of the infectious period as reported in \(^{63,64} \).

Under the assumption that no serological/virological/antigenic test is done before vaccine administration, the vaccine is administered to all individuals, except for clinical cases who show clear signs of the disease or individuals that were detected as infected by the TTI in place. In our model a vaccine administered to infected or recovered individuals has no effect.

In the baseline scenario we parametrise \( V E_{SP,1} \), \( V E_{SP,2} \), \( V E_{S,1} \) and \( V E_{S,2} \) by taking values in the middle of estimates reported in the systematic review by Higdon and collaborators \(^7 \) for the Comirnaty vaccine and the Delta variant \(^{65} \). Chosen values of \( V E_{SP,2} \) and \( V E_{S,2} \) are also comparable with the effectiveness estimates reported in a meta-analysis for the Delta variant, complete vaccination, all vaccines combined \(^{18} \). We also test values on the upper and lower
extremes of the range of estimates of $^{17}$. Parameters are listed in Table S2 of the Supplementary Information.

**Test-trace-isolate**

We model a baseline TTI accounting for case detection, household isolation and manual contact tracing. Fifty percent of individuals with clinical symptoms were assumed to get tested and to isolate if positive. We assume an exponentially distributed delay from symptoms onset to case detection and its isolation with 3.6 days on average. Once a case is detected, his/her household members isolate with probability $p_{ct,HH}$, while other contacts isolate with probabilities $p_{ct,A}$ and $p_{ct,Oth}$, for acquaintances and sporadic contacts, respectively. In addition to the detection of clinical cases, we assume that a proportion of subclinical cases were also identified (10%). Isolated individuals resume normal daily life after 10 days unless they still have clinical symptoms after the time has passed. They may, however, decide to drop out from isolation each day with a probability of 13% if they do not have symptoms $^{66}$.

In the scenario of virus re-introduction we consider enhanced TTI, corresponding to a situation of case investigation, screening campaign and sensibilisation (prompting higher compliance to isolation). We assume a higher detection of clinical and subclinical cases (70% and 30%, respectively), perfect compliance to isolation by the index case and household members and a three-fold increase in contacts identified outside the household.

Step-by-step description of contact tracing is provided in the Supplementary Information. Parameters for baseline TTI are provided in Table S3, while parameters for enhanced TTI are provided in Table S4.

**Vaccination strategies**

A vaccine opinion (willingness or not to vaccinate) is stochastically assigned to each individual at the beginning of the simulation depending on age (below/above 65 years old). Opinion does not change during the simulation. In some scenarios we assume that all individuals are willing to accept the vaccine in case of reactive vaccination, while maintaining the opinion originally assigned to them when the vaccine is proposed in the context of non-reactive vaccination. Only individuals above a threshold age, $a_{th,V}=12$ years old, are vaccinated. We assume that a certain fraction of individuals are vaccinated at the beginning of the simulation according to the age group ([12,60], 60+). We compare the following vaccination strategies:

- Mass: $V_{\text{daily}}$ randomly selected individuals are vaccinated each day until a $V_{\text{tot}}$ limit is reached.
**Workplaces/universities:** Random workplaces/universities are selected each day. All individuals belonging to the place, willing to be vaccinated, and not isolated at home that day are vaccinated. Individuals in workplaces/universities are vaccinated each day until the daily limit, $V_{\text{daily}}$, is reached. No more than $V_{\text{tot}}$ individuals are vaccinated during the course of the simulation. We assume that only workplaces with $\ell \cdot \ell \cdot 20$ employees or larger implement vaccination.

**School location:** Random schools, other than universities, are selected each day and a vaccination campaign is conducted in the places open to all household members of school students. All household members willing to be vaccinated, above the threshold age and not isolated at home that day are vaccinated. No more than $V_{\text{daily}}$ individuals are vaccinated each day and no more than $V_{\text{tot}}$ individuals are vaccinated during the course of the simulation.

**Reactive:** When a case is detected, vaccination is done in her/his household with rate $r_{\text{V}}$. When a cluster – i.e. at least $n_{\text{cl}}$ cases detected within a time window of length $T_{\text{cl}}$ – is detected in a workplace/school, vaccination is done in that place with rate $r_{\text{V}}$. In the baseline scenario, we assume vaccination in workplace/school to be triggered by one single infected individual ($n_{\text{cl}}=1$). In both household and workplace/school, all individuals belonging to the place above the threshold age and willing to be vaccinated are vaccinated. Individuals that were already detected and isolated at home are not vaccinated. No more than $V_{\text{daily}}$ individuals are vaccinated each day and no more than $V_{\text{tot}}$ individuals are vaccinated during the course of the simulation. In the baseline scenario these quantities are unlimited, i.e. all individuals to be vaccinated in the context of reactive vaccination are vaccinated.

Parameters and their values are summarised in Table S5 of the Supplementary Information.

**Data availability**

The synthetic population used in the analysis is available on github.

**Code availability**

We provide all C/C++ code files of the model on github.

**Test-trace-isolate**

We model case detection and isolation, combined with tracing and isolation of contacts according to the following rules:

- As an individual shows clinical symptoms, s/he is detected with probability $p_{d,c}$. If detected, case confirmation and isolation occur with rate $r_d$ upon symptoms onset.

- Subclinical individuals are also detected with probability $p_{d,sc}$, and rate $r_d$. 

(*) Mid range estimate in $^7$, $V_{E_{SP}}=55\%$, leads to a value of $p_{V}>1$, thus $V_{E_{SP}}=53\%$ is taken.
• The index case’s household contacts are isolated, with probability $p_{ct,HH}$, the same time the index case is detected and isolated. We assume that these contacts are tested at the time of isolation and among those all subclinical, clinical, pre-subclinical, and pre-clinical cases are detected (testing sensitivity 100%).

• Once the index case is detected, contacts of the index case occurring outside the household are traced and isolated with an average delay $r_{ct}^{-1}$. We define an acquaintance as a contact occurring frequently, i.e. with a frequency of activation higher than $f_a$. We assume that an acquaintance is detected and isolated with a probability $p_{ct,A}$, while other contacts (i.e. sporadic contacts) are detected and isolated with probability $p_{ct,sp}$, with $p_{ct,A} > p_{ct,sp}$. We assume that traced contacts are tested at the time of isolation and among those all subclinical, clinical, pre-subclinical, and pre-clinical cases are detected (testing sensitivity 100%).

• Only contacts (among contacts occurring both in household and outside) occurring within a window of $D$ days before index case detection are considered for contact tracing.

• The index-case and the contacts are isolated for a duration $d_i$ (for all infected compartments) and $d_s$ (for susceptible and recovered compartments). Contacts with no clinical symptoms have a daily probability $p_{drop}$ to drop out from isolation.

• For both the case and the contacts, isolation is implemented by assuming no contacts outside the household and transmission risk per contact within a household reduced by a factor $\iota$.

Parameter values are reported in Table S3 and Table S4 for baseline and enhanced TTI, respectively.

### Details on the epidemic simulations

A schematic representation of the main program and of the simulation code and of the algorithm used for a single stochastic realisation are shown in Figure S1 and S2, respectively. Simulations are discrete-time and stochastic. At each time step, corresponding to one day, three processes occur (Figure S2):

- **Vaccination Step**: vaccines are administered according to the strategy or the strategies’ combination.

- **Testing Step**: cases are detected and isolated; contacts (within and outside household) are identified and isolated; isolated individuals get out from isolation.

- **Transmission Step**: infectious status of nodes is updated. This includes transmission, recovery and transition through the different stages of the infection (e.g. from exposed to pre-symptomatic, from pre-symptomatic to symptomatic).
Figure S1. Algorithm of the main program. (drawn with code2flow.com)
A single-run simulation is executed with no modelled intervention, until the desired immunity level is reached. This guarantees that immune individuals are realistically clustered on the network. We added some noise, by reshuffling the immune/susceptible status of 30% of the nodes to account for travelling, infection reintroduction from other locations and large gathering with consequent super-spreading not accounted for by the model. In Figure 2 and 3 of the main paper, all processes (transmission, TTI, vaccination) are simulated from the beginning of the simulation. In the scenario with virus re-introduction (Figure 4), TTI and mass vaccination are modelled from the beginning. TTI is enhanced from the detection of the first
case. Reactive vaccination starts after the detection of the first $n_{RV}$ cases, with $n_{RV}=1,5,10$

explored.

We vary COVID-19 transmission potential by tuning the daily transmission rate per contact $\beta$.

The reproductive number $R$ is computed numerically as the average number of infections each infected individual generates throughout its infectious period at the beginning of the simulation. We tune $\beta$ to have the desired $R$ value (1.6 for the analysis in the main text) for the reference scenario - i.e. with only vaccination at the start. We then compare different vaccination strategies at the same value of transmissibility $\beta$.

To calibrate the duration of the pre-symptomatic stage from 2 (value reported in Table S1) we generated an output file containing the list of all transmission events with the infection status of the infector. The proportion of pre-symptomatic transmission was computed as the fraction of transmission events with infector in the compartment $I_{p,sc}$ or $I_{p,c}$ over all infection events.

**Additional Results**

**Comparison between reactive and non-reactive vaccination strategies**

**Vaccinated settings**

We provide here a detailed analysis of the time evolution of the number of settings where vaccines are deployed in the context of reactive vaccination.

![Figure S3. A, B Daily number of workplaces (A) and schools (B) where vaccines are deployed in the context of reactive vaccination. C Size of workplaces/Schools where vaccines are deployed as a function of time. Values are means over 2000 stochastic simulations. Shaded areas indicate the standard errors.](image)
Sensitivity analysis

We compare here reactive vaccination with non-reactive vaccination strategies under a variety of epidemic scenarios.

In Figure S4 we compare all strategies at equal number of doses over the two month period, exploring the impact of the following parameters: reproductive ratio, immunity level of the population, repartition of contacts across settings due to social distancing, incubation period, effect of the vaccine in the infection duration, vaccine uptake, and time between doses.

Except when otherwise indicated, parameters are the ones of Figure 2 D, E of the main paper, i.e. intermediate vaccination coverage at the beginning (~45% of the whole population vaccinated), moderate/high initial incidence and the vaccine uptake to be the same for all strategies. Increasing the transmissibility or initial immunity reduces the impact of reactive vaccination (panel A, B). In panel C we explore the impact of teleworking and reduction in community contact by comparing the baseline scenario with scenarios with no or stronger restrictions. Reactive vaccination becomes more effective when no restriction is in place - although the effect is not strong. This is likely due to the enhanced role of workplaces as a setting of transmission when no teleworking is in place, thus bringing to an increased benefit of reactive vaccination targeting this setting. In panel D, we analyse the impact of the choice of the incubation period exploring incubation period values ranging from 5.1 to 6.3. We find that results are highly robust to the choice of the parameters, within this range. In panel E we compare different hypotheses regarding the effect of the vaccine on the infection duration, i.e. the baseline case with the case in which the vaccine induces no reduction in the infectious duration. Also in this case, results are robust. Eventually in panel F we compare different levels of vaccine uptake, assuming uptake to be the same in all strategies as in Figure 2 of the main paper. The impact of vaccination increases with the uptake, the effect being stronger for the reactive strategy. Eventually, we compare in panel G different timing for vaccine-induced immunity to become effective. Specifically, we consider a case in which partial protection against infection mounts one week after the first dose. Assuming an incubation period of ~6 days, this would be consistent with no reduction in cases observed ~2 weeks after first-dose inoculation, as reported by some real vaccine effectiveness studies. We then consider a longer interval between doses (i.e. 4 and 8 weeks). Assuming that protection against infection starts one week after first-dose inoculation leads to a higher impact of vaccination for all four vaccination strategies.
Figure S4. Relative reduction (RR) in the attack rate (AR) after two months for all strategies at equal number of doses. RR is computed with respect to the reference scenario with initial vaccination only. Different parameter values and modelling assumptions are compared. Vaccination rate for mass, workplaces/universities and school location vaccination is set to the average value recovered for reactive vaccination. Exceptions made for the parameter explored in each panel - indicated in the x-axis -, all parameters are as in panel D, E of Figure 2 of the main paper. Parameters explored are: \( A \) reproductive ratio; \( B \) natural immunity of the population at the start; \( C \) repartition of contacts across settings due to social distancing (Intermediate is the baseline scenario, while high is given by a 30% reduction in community contacts and a 20% of individuals doing teleworking); \( D \) incubation period, \( E \) vaccine-induced reduction in infection duration (yes, no), \( F \) vaccine uptake, and \( G \) time between doses - the x-axis labels wNwM indicates the average number of weeks, N and M, of no protection following first dose inoculation and of intermediate vaccine effectiveness, respectively. Values are means over 2000 stochastic simulations. Error bars are derived from the standard errors of the AR. These are smaller than the size of the dots in almost all cases.
The impact of reactive vaccination and its demand in terms of vaccine doses varies depending on the incidence level. In Figure S5 A-C we compare all strategies under a scenario of flare-up of cases. We assumed three cases were infected at the beginning. Panels A, B of Figure S5 are the analogous of panel B, E of the Figure 2 of the main paper and are obtained with the same parameters exception made for the value of initial incidence - notably, we assumed intermediate vaccination coverage at the beginning (~45% of the whole population vaccinated) and the vaccine uptake to be the same for all strategies. Panel A shows the relative reduction in the attack rate after two months as a function of the number of first daily doses, while Panel B compares the incidence profiles under different strategies at equal number of vaccine doses. The relative reduction produced by reactive vaccination is close to the one produced by mass, school location and workplaces/universities. Panel C shows the number of vaccines deployed each day for reactive vaccination and the number of workplaces/schools where vaccines are deployed. These are initially low and increase gradually with incidence.

We then explore the impact of the reactive vaccination within the flare-up case in varying the different parameters. Specifically, we compare all strategies at an equal number of doses, varying the level of social distancing (Figure S5 D, analogously to Figure S4 C) and the timing for the immunity to mount after the first-dose vaccination (Figure S5 E, analogous to Figure S4 G). For certain parameter values reactive vaccination produces a higher relative reduction in the attack rate compared with non-reactive strategies. This is the case for instance when the development of vaccine immunity is rapid, and when no social restrictions are in place. In other cases it produces comparable effect. This is the case for instance of long delays between doses. Finally, in Figure S5 F, we provide an overview of the impact of initial incidence. As initial incidence increases the advantage of the reactive vaccination compared with the non-reactive strategies increases.
**Figure S5.**

A Relative reduction (RR) in the attack rate (AR) over the first two months for all strategies as a function of the vaccination pace. RR is computed with respect to the reference scenario, with initial vaccination only. AR is computed from clinical cases.

B Incidence of clinical cases with different vaccination strategies. The reactive and non-reactive scenarios plotted are obtained with the same average daily number of vaccines, i.e. 55 daily first-dose vaccinations per 100,000 inhabitants.

C Number of daily first-dose vaccinations, and workplaces/schools (WP/S in the plot) where vaccines are deployed.

D AR RR after two months according to the repartition of contacts across settings due to social distancing - Intermediate is the baseline scenario, while high is given by a 30% reduction in community contacts and a 20% of individuals doing teleworking.

E AR RR after two months according to the timing for the immunity to mount after first-dose vaccination - the x-axis labels wNwM indicates the average number of weeks, N and M, of no protection following first dose inoculation and of intermediate vaccine effectiveness, respectively.

F AR RR after two months according to the initial incidence for all strategies at equal number of doses. In panels D-F all strategies are compared at equal number of doses. All panels, except for panel F, consider a flare up scenario, where the epidemic is seeded with 3 infectious individuals. All other parameters are as in panels D, E of Figure 2 of the main paper. Values are means over 2000 stochastic simulations. Error bars in panels A, D, E, F are derived from the standard errors of the AR. Shaded areas in panels B, C, indicate the standard errors.

**Additional epidemic outcomes**

Based on the estimated incidence of clinical cases per day provided by the transmission model, we infer outcomes related to hospital, namely hospital and intensive care unit (ICU) entries, beds in ICU ward, and deaths. We use age-dependent hospital admissions (ICU and non-ICU) risks estimated by 16,17 and ICU admission risks for hospitalised patients based on SI-VIC extract 18. Hospital admissions risks were adjusted to apply only to clinical cases 19 and
to account for vaccine effectiveness for hospitalisation for zero, half (1 dose) and full (2
doses) vaccination. We assumed the vaccine efficacies for hospitalisation were equal to 83%
and 94% for half and full vaccinations, respectively. We also assume that the hospital
admission risk increases by 80% with the Delta variant compared to Alpha and by 40% with
the Alpha variant compared to the wild type. Patients who were hospitalised entered the
hospital on average 7 days (sd = 3.9 days – Gamma distribution) after the beginning of the
infectious phase. Those who were admitted in ICU enter this unit with a mean delay of 1.69
days (assuming an exponential distribution). To estimate the number of occupied beds, we
use age-specific mean durations of stay and their corresponding standard deviations in ICU
calculated on all the hospitalised cases in the first 9 months of the French epidemic (March-
November 2020). We assume that the standard deviations of ICU lengths of stay were equal
to the corresponding mean and do not consider post-ICU care in the estimation of occupied
beds. We estimate the number of deaths using hospital and ICU death risks of hospitalised
infected persons. Deaths are delayed in time using the mean delays and standard
deviations from hospital or ICU admission to death. All lengths of stay are supposed to
follow a Gamma distribution. Parameters and their values are summarised in Tables S6 and
S7.

We also estimate the number of life years and quality-adjusted life years (QALY) lost for each
death using life-tables provided by ‘French National Institute of Statistics and Economic
Studies’ (INSEE) for 2012-2016 and utility measures of each age-group in France.

Figure S5 shows the relative reductions in the number of hospitalisations, deaths, ICU entries, life-year lost, quality-adjusted life-year lost and ICU bed occupancy at the peak, comparing each vaccination scenario with the reference scenario - i.e. vaccination only at the start. We consider here the high incidence and intermediate vaccine coverage scenario, analogously to Figure 2 D, E of the main paper. The six indicators show a behaviour similar to incidence.
Overall reduction values are smaller. This is expected, since a large proportion of elderly are already vaccinated at the start, and the compared vaccination strategies target a population that is less at risk of severe infection. Still all indicators show the same qualitative behaviour, with reactive vaccination outperforming the non-reactive vaccination strategies at equal number of first-dose vaccination.

**Figure S6.** A, B, C, D, E Relative reduction (RR) in the cumulative incidence of hospitalisations, intensive care unit (ICU) entries, deaths, life years (LY) lost and quality-adjusted life years (QALY) lost over the first two months for all strategies as a function of the vaccination pace. F Relative reduction (RR) in occupied ICU beds at the peak over the first two months for all strategies as a function of the average daily number of first-dose vaccinations for the intermediate vaccination coverage scenario. Values are means over 2000 stochastic simulations. Error bars are derived from the standard errors of the AR. Parameters are the same as in Figure 2 D, E of the main paper.

**Combined reactive and mass vaccination for managing sustained COVID-19 spread:**

**Additional results**

In Figure S7 we show the incidence curve corresponding to the scenarios analysed in Figure 3 A of the main paper. Mass and combined vaccination with the five different vaccination paces are compared.
Figure S7. Incidence of clinical cases for mass and combined vaccination strategies for three different vaccination paces. Scenarios are the same as the ones plotted in Figure 3 A. We assumed the following parameters: initial incidence of clinical cases 160 per 100 000 inhabitants; $R=1.6$; Initial immunity 32%; vaccinated at the beginning 90% and 40% for 60+ and <60, respectively; 10% of individuals are doing teleworking and 5% of community contacts are removed. Values are means over 2000 stochastic simulations. Shaded areas indicate the standard errors - very low for this set of parameters.

Combined reactive and mass vaccination for managing a COVID-19 flare-up

Additional results

In Figure S8 we show the incidence curve corresponding to the scenarios analysed in Figure 4 of the main paper. Mass and combined vaccination with the different vaccination scenarios considered are compared.
Figure S8. Incidence of clinical cases for mass and combined vaccination strategies for the scenarios analysed in Figure 4 of the main paper. **A** scenario with enhanced TTI. **B** scenario with baseline TTI. In all panels we assumed the following parameters: $R=1.6$; Initial immunity 32%; 90% for 60+ year old and 40% for <60 years old already vaccinated at the beginning; 10% of individuals are doing teleworking and 5% of community contacts are removed. Values are means over 8000 stochastic simulations. Shaded areas indicate the standard errors.

Sensitivity analysis

In Figure S9 we analyse the impact of combined and mass vaccination in a flare up scenario similarly to Figure 4, by varying the hypotheses on virus transmissibility and vaccine escape. Specifically we consider values of the reproductive ratio from 1.2 to 1.8, and both worst and baseline vaccine effectiveness level - the worst vaccine effectiveness level is the same as in Figures 2 I of the main paper. Analogously to Figure 4 we compare the attack rate for combined and mass vaccination, assuming both baseline and enhanced TTI and both baseline and 100% vaccine uptake in the context of reactive vaccination. We consider only the case in which reactive vaccination starts after the detection of the first case. For each set of parameters, scenarios with enhanced TTI and 100% uptake are associated with smaller attack rates and larger difference between mass and combined than the corresponding scenarios with baseline TTI and baseline uptake.
Figure S9. Average attack rate per 100000 inhabitants after two months for the flare up case under different hypotheses: A, B, R = 1.8 with baseline vaccine effectiveness; C-H worst vaccine effectiveness with R = 1.2 (C,D), R = 1.6 (E,F) and R = 1.8 (G,H). The worst vaccine effectiveness scenario is defined as in figure 2 I, i.e. $V_{E,S,1} = 30\%$, $V_{E,SP,1} = 35\%$, $V_{E,S,2} = 53\%$ and $V_{E,SP,2} = 60\%$. We compare enhanced and baseline TTI - A, C, E, G and B, D, F, H, respectively -, as well as baseline and 100% vaccine uptake. In all panels, parameters are the same as in Figure 4: initial immunity 32%; 90% for 60+ year old and 40% for <60 years old already vaccinated at the beginning; 10% of individuals are doing teleworking and 5% of community contacts are removed. Values are means over 8000 stochastic realisations. Error bars are the standard error.

We then investigate the impact of combined and mass vaccination on the extinction of the flare-up. In Figure 10 A we plot the probability of extinction for the scenario considered in Figure 4 A of the main paper (enhanced TTI and 100% vaccine uptake). We find that the probability of extinction is $\sim 5\%$, and the difference between mass and combined is $\sim 0.5\%$. The probability of extinction progressively increases under more optimistic hypotheses: increase in case detection from 70% and 30% (enhanced TTI) to 100% and 50% (strong TTI) for clinical and subclinical cases, respectively; increase in vaccine effectiveness to the best case scenario considered in Figure 2 I; rapid mounting of the vaccine effect, with partial immunity against infection already present one week after inoculation. In the best-case scenario plotted in panel H, the probability of extinction reaches $\sim 0.15$ and $\sim 0.18$ for mass and combined vaccination, respectively.
Figure S10. Probability of extinction for an outbreak of three initial cases for mass vs. combined vaccination, compared at an equal number of doses. Three sets of parameters are investigated. 1) Baseline vaccine effectiveness (A,B,E,F) vs best effectiveness, i.e. $V_{E,1} = 65\%$, $V_{E,SP,1} = 75\%$, $V_{E,2} = 80\%$ and $V_{E,SP,2} = 95\%$, (C,D,F,H); 2) enhanced TTI (A,C,E,G) vs. strong TTI with $p_{d,c} = 1$ and $p_{d,sc} = 0.5$ (B,D,F,H). 3) 2 weeks (baseline) for vaccines to reach partial effectiveness (A,B,C,D) vs 1 week (E,F,G,H). In all panels, parameters are the same as in Figure 4: initial immunity 32%; 90% for 60+ year old and 40% for <60 years old already vaccinated at the beginning; 10% of individuals are doing teleworking and 5% of community contacts are removed. Values are means over 15000 stochastic realisations. Error bars are the standard error.
