Short Title: SES and unemployment under COVID-19 in Japan

Two tables and no figure (excluding one supplemental table)

Abstract

Background: This study examined the relationship between socioeconomic status (SES) and subsequent unemployment.

Methods: This prospective cohort study was conducted using a self-administrated questionnaire in Japan. SES, personal characteristics, and occupation of recruited workers were surveyed at baseline (December 22-25, 2020); subsequent unemployment was examined at follow-up (February 18-19, 2021). We determined the odds ratios (ORs) of unemployment for SES and other variables using a multilevel logistic model.

Results: Among all 19,941 participants, 2.3% reported experience of unemployment through negative reasons. Multivariate analysis showed the OR and 95% confidence interval for unemployment associated with age to be 0.66 (0.47-0.92) for 30-39 years, 0.36 (0.25-0.51) for 40-49, 0.36 (0.25-0.53) for 50-59, and 0.43 (0.27-0.67) for more than 60 compared with 20-29 years. The association with annual household income was 2.96 (1.94-4.50) for <2 million yen and 1.51 (1.03-2.22) for 2-4 million yen compared with >10 million yen. The association with marital status was 1.43 (1.04-1.98) for bereaved/divorced compared with married (working spouse). The association with occupation was 1.75 (1.35-2.29) for temporary or contract employees and 2.11 (1.04-4.30) for agriculture, forestry, or fishing compared with general employees. The association with job type was 1.69 (1.34-2.15) for

58 mainly manual labor.

59 **Conclusion:** We observed a relationship between SES and subsequent unemployment under

60 COVID-19. It is necessary to provide broad, ongoing support in the form of both short-term

61 assistance and long-term job training and health care.

63 **Keywords:** socioeconomic status, unemployment, COVID-19, Japan

Introduction

Economies around the world have been hard hit by COVID-19.[1] Employment is generally

dependent on the economy, and so poor economic conditions have increased unemployment

[2,3]. COVID-19 has likewise had an impact on employment in Japan; however, the increase in

the unemployment rate is less than that after the collapse of Lehman Brothers[4]. Data indicate

that the number of employed people is declining[4].

Socioeconomic status (SES) has a great influence on unemployment[5-7], and it is

connected with a significant risk of deteriorating physical and mental health[8-10]. Thus,

unemployment is an important factor with respect to public health. Research has shown that

people with low education tend to become non-regular workers; once they become

non-regular workers, it is difficult to return to full-time employment. Such individuals are

more likely to work in unstable conditions[11-13].

With COVID-19, it is assumed that such vulnerable workers would make a significant

contribution to unemployment owing to poor economic and business conditions. One study

reported a relationship between SES and employment during COVID-19 in the United

States[14]. However, that was a cross-sectional study; to the best of our knowledge, no cohort

studies have examined the association between SES and employment status. The present

cohort study aimed to clarify the relationship between SES and subsequent unemployment

under the pandemic.

Methods

This prospective cohort study about COVID-19 among Japanese workers was conducted

under the Collaborative Online Research on the Novel-coronavirus and Work

(CORoNaWork) Project. Details of the study protocol are described elsewhere[15]. Briefly, we

administered a baseline questionnaire on December 22–25, 2020 and a follow-up

questionnaire on February 18–19, 2021, when Japan was in its third pandemic wave.

For the baseline survey, we recruited 33,087 workers throughout Japan from 605,381

randomly selected panelists registered with an Internet survey company. The inclusion

criteria for participants were being currently employed and aged 20–65 years. This study

excluded health-care professionals and caregivers. We applied cluster sampling with

stratification by sex, job type, and region. We excluded 6051 invalid responses owing to the

following: response time <6 minutes; body weight <30 kg; height <140 cm; inconsistent

answers to similar questions; and incorrect answers to questions intended to identify

fraudulent responses. We distributed the follow-up questionnaire to the 27,036 people with

valid responses to the baseline questionnaire. In total, 19,941 participants completed both

questionnaires (follow-up rate, 73.8%).

This study was approved by the Ethics Committee of the University of Occupational

and Environmental Health, Japan (reference nos. R2-079 and R3-006). Informed consent was

obtained from all participants.

Explanatory variables

We retrieved the following data from the baseline survey for inclusion as explanatory

variables: age; sex; SES (based on annual household income and education); marital status;

occupation; and job type. We categorized age into the following five groups: 20–29; 30–39;

40–49; 50–59; and ≥60 years. Annual household income was classified into the following

four groups: under 2 million; 2–4 million; 4–6 million; 6–8 million; 8–10 million; and >10

million yen. We categorized education into five groups: up to junior high school; up to high

school; up to junior college or technical school; up to university; and graduate school. Marital

status was classified into four groups: married (working spouse); married (spouse not

working); divorced or widowed; and never married. We categorized occupation into 10

groups: general employee; manager; executive manager; public employee, faculty member,

or non-profit organization employee; temporary or contract employee; self-employed; small

office home office; agriculture, forestry, or fishing; professional occupation (e.g., lawyer, tax

accountant, medical-related work); and other. Job type was classified into three categories:

mainly desk work; work mainly involving interpersonal communication; and mainly manual

or physical labor.

Outcomes

We ascertained unemployment as follows. First, the baseline survey included only people

who were employed at the time of response. In the follow-up survey, in answer to the

question "Have you changed your place of work since December 2020?" respondents were

asked to select one of the following six options: "no change"; "I was transferred to another

company"; "I resigned and got a new job right away"; "I stopped working and was

unemployed for a while but am now working"; "I stopped working and started a business

(e.g., managing a company, running a sole proprietorship, or engaging in self-employment)";

and "I stopped working and am not currently working (including job seeking)." We wanted to

identify unemployment status owing to negative reasons with respect to the research

objectives; thus, we defined unemployment using the responses of "I stopped working and

was unemployed for a while but am now working" and "I stopped working and am currently

not working (including job seeking)." For a sensitivity analysis, we also used unemployment

regardless of the reason for that status as a secondary outcome; we selected the options

excluding "no change" and "I was transferred to another company."

Control variables

We set self-rated health from the baseline survey as a control variable. We made the

following request: "Please choose the option that best describes your overall health condition,

including both physical and mental health." There were five response options: extremely

good; very good; good; fair; and poor.

Statistical analysis

We determined the odds ratios (ORs) of unemployment because of negative reasons for SES

and other variables using a multilevel logistic model for the prefecture of residence. The

multivariate model was adjusted for sex, age, annual household income, educational

background, marital status, occupation, job type, and self-rated health. For the sensitivity

analysis, we conducted the same analysis with unemployment regardless of the reason as the

outcome. We undertook a trend test by conducting the analysis using age, annual household

income, and education as continuous variables. We also used the incidence rate of COVID-19

by prefecture as a prefecture-level variable. The multilevel analysis was performed within

this incidence rate of COVID-19. We considered P values under 0.05 statistically significant.

All analyses were conducted using Stata (Stata Statistical Software release SE16.1; StataCorp

LLC, College Station, TX, USA).

Results

The basic characteristics of the respondents appear in Table 1. There were 11,170 men in the

sample, accounting for 56% of the total. The mean age was 48.0 years.

Table 2 shows the associations of SES and other factors with unemployment owing to

negative reasons: 454 (2.3%) workers reported unemployment for such reasons. Multivariate

analysis showed that the OR and 95% confidence interval (CI) of unemployment associated

with age was 0.66 (0.47–0.92) for 30–39 years, 0.36 (0.25–0.51) for 40–49 years, 0.36

(0.25–0.53) for 50–59, and 0.43 (0.27–0.67) for ≥60 years compared with 20–29 years. The

association with annual household income was 2.96 (1.94–4.50) for <2 million yen and 1.51

(1.03–2.22) for 2–4 million yen compared with >10 million yen. The association with marital

status was 1.43 (1.04–1.98) for bereaved or divorced compared with married (spouse

working). The association with occupation was 1.75 (1.35–2.29) for temporary or contract

employees and 2.11 (1.04–4.30) for agriculture, forestry, or fishing compared with general

employees. The association with job type was 1.69 (1.34–2.15) for mainly manual or physical

labor.

Table A1 presents the associations of SES and other factors with unemployment

regardless of the reason in a sensitivity analysis. In all, 725 (3.6%) workers had experienced

unemployment for any reason. The OR and 95%CI of unemployment associated with sex was

1.20 (0.99–1.44) for women compared with men; that was different from result with the

analysis of unemployment owing to negative reasons. For the other variables, the results were

similar to those of unemployment owing to such reasons.

Discussion

This study found that the following were at high risk of unemployment; younger people; individuals with lower income; being unmarried owing to divorce or bereavement; temporary employees; people working in agriculture, forestry, or fisheries; and blue-collar workers. One US[14] study examining the relationship between socioeconomic disparity and unemployment under COVID-19 reported that racial minorities and low-income earners tended to be more unemployed; low-income earners were more than twice as likely to be unemployed. The present study revealed an over twofold difference in the unemployment rate between older workers and those in their 20s. The unemployment rate for workers earning under 4 million yen annually was also high. These findings indicate that unskilled workers with fewer years of experience were greatly affected. Salaries are usually higher with a greater level of specialization and more sophisticated job content. Low-income workers are more likely to be employed in less specialized, replaceable work.

This study also found that low-income workers were more than twice as likely to be

unemployed as full-time workers. Non-regular workers and young people are more prone to

be unemployed. Non-regular workers tend to be the first to lose their jobs when business

conditions deteriorate: they act as a kind of adjustment valve for company employment.

Under COVID-19, one labor force survey in Japan revealed that the number of non-regular

workers dropped sharply[4]. There appears to be a tendency for such vulnerable workers to

become unemployed more readily. We also found that blue-collar workers, agriculture,

forestry, and fishery workers, and unmarried workers had higher unemployment rates.

Agriculture covers an area of employment that is inherently less susceptible to economic

fluctuations; thus, the reason for the high unemployment in agriculture we found is unclear.

However, temporary employment during the farming season is common[16,17] in Japan. Over

80% of temporary workers have short-term contracts of under one month; accordingly, our

results may have reflected the trends among such workers.

241   Yamamoto's study[18] revealed that single, blue-collar, non-regular workers are more

likely than other people to choose non-regular employment unwillingly. Their behavior in

choosing job types and transitioning between jobs is similar to that of unemployed people;

they are under more stress than willing part-time workers. It is necessary to provide support

for such individuals. The minimum hourly wage in Tokyo was about 1000 yen in 2020 [19]. If

people work 40 hours a week at the minimum wage, the annual income will be around 2

million yen. Non-regular workers who are unable to work longer hours, such as through

illness, face difficulties and are more affected by unemployment trends. It has been shown[20]

that individuals with lower annual incomes are more likely to discontinue treatment under

COVID-19; thus, both health and financial support are needed.

Public efforts to support unemployment during the pandemic have begun in Japan.

The government provides subsidies for companies having financial difficulties to help protect

their employees. Japan's Ministry of Health, Labor and Welfare provides a wide range of

support measures for people in need and the unemployed. It is necessary to support both

companies and employees. For example, individuals who have to deal with sudden

unemployment can apply to the government to borrow 200,000 yen as an emergency small

loan. As of July 10, 2021, over 2.5 million people applied for such loans, and over 2.4 million

received them[21]. Conventional systems to promote and stabilize employment (such as labor

policies for young people, promoting non-regular employees to regular positions, and career

development subsidies) are also available.

In addition to support through subsidies, it is necessary to provide continuous social

security. If unemployed and irregular workers receive more self-development help and job

training, it becomes easier for them to achieve regular employment[22,23]. However, the

on-the-job training rate among non-regular employees is about half that of regular one[24]. We

need to help them to get education.

This study has several limitations. First, the reason for the participants'

unemployment was unclear. We do not know if it was due to the effects of COVID-19, if a

company went bankrupt, or if participants tried to change jobs of their own accord. However,

we analyzed unemployment using two different definitions, and the results with both were

almost identical. Second, the generalizability of our results is unclear because the study was

conducted using an Internet surveys. Individuals who were truly in need may not have had

Internet access and thus could not have participated in the survey. We attempted to reduce as

much bias in the target population as possible by sampling according to region, job type, and

prefecture based on the infection incidence rate. Third, among the 27,036 participants in the

baseline survey, 7095 did not respond to the follow-up survey (non-participation rate, 26%).

It is possible that some respondents were unable to participate in the follow-up survey owing

to poverty caused by unemployment. However, if such individuals had participated in the

survey, the association between SES and unemployment would have been stronger.

In conclusion, we identified a relationship between SES and subsequent

unemployment during COVID-19. It is necessary to provide broad, ongoing support in the

form of both short-term assistance and long-term job training and health care.
