Keywords: amygdala, fMRI, loneliness, striatum, social anxiety

1 **Abstract**

2

3 Loneliness is a public health concern with detrimental effects on physical and mental well-
4 being. Given phenotypical overlaps between loneliness and social anxiety, cognitive
5 behavioral interventions targeting social anxiety might be adopted to reduce loneliness.
6 However, it is still elusive whether social anxiety and loneliness share the same underlying
7 neurocognitive mechanisms. The current study aimed at investigating to what extent known
8 behavioral and neural correlates of social avoidance in social anxiety are evident in loneliness.
9 We used a pre-stratified approach involving 42 participants with high and 40 control
10 participants with low loneliness scores. During functional magnetic resonance imaging (fMRI),
11 the participants completed a social gambling task to measure the subjective value of engaging
12 in a social situation and responses to positive and negative social feedback. Uni- and
13 multivariate analyses of behavioral and fMRI data replicated known task effects across groups.
14 However, although lonely participants were characterized by increased social anxiety,
15 loneliness was associated with a response pattern clearly distinct from social anxiety.
16 Specifically, Bayesian analyses revealed moderate evidence for equal subjective values of
17 engaging in social situations and comparable amygdala responses to social decision-making
18 and striatal responses to positive social feedback in both groups. Conversely, lonely
19 participants showed significantly altered behavioral responsiveness to negative feedback and
20 opposing striatal brain activity and connectivity compared to controls. Our findings suggest that
21 loneliness is associated with altered emotional reactivity to social situations rather than
22 behavioral tendencies to withdraw from social interactions. Thus, established interventions for
23 social anxiety should be adjusted when targeting loneliness.

24 Introduction

25 Loneliness is a painful condition which can be a catalyst for subjective stress [1] and is
26 associated with detrimental effects on mental and physical health [2,3]. As such, loneliness
27 has been identified as a risk factor for premature mortality comparable with smoking or obesity
28 [4,5]. Consequently, loneliness has come into focus of politics and clinicians as a major public
29 health concern with high economic costs for society [6-8]. With social distancing in place in
30 most countries around the world, COVID-19 is expected to have vast impact on physical and
31 mental health, particularly in people inflicted by poor resilience to social adversity due to pre-
32 existing low levels of social integration [9,10]. Preliminary evidence indicate that the prevalence
33 of loneliness might have increased due to the ongoing COVID-19 pandemic, which
34 emphasizes the urgent need of interventions to target loneliness [11-14].

35 Recent findings highlight a close link of loneliness with social anxiety symptoms [15-17] and
36 identified social anxiety as predictor for future loneliness [18-20]. For instance, social anxiety
37 was found to be consistently associated with social isolation, lower perceived social support,
38 and decreased relationship satisfaction [21-23]. Moreover, poor friendship quality promotes
39 increases in social anxiety symptomatology [24]. A perceived discrepancy in the quality and
40 quantity of the actual and desired relationships, in turn, is a key feature of loneliness [25].
41 Likewise, safety behavior such as the avoidance of social situations is known to be a core
42 mechanism fostering the maintenance of social anxiety and is also hypothesized to be
43 preferred by lonely individuals [26,27].

44 Given the phenotypical overlap between loneliness and social anxiety, cognitive behavioral
45 therapies targeting social anxiety might be co-opted as interventions to reduce loneliness.
46 Existing programs are often based on cognitive models of social anxiety [28], which posit an
47 exaggerated fear of evaluation as a core etiological mechanism of psychopathology. Indeed,
48 current neurocircuitry models of social anxiety disorder emphasize amygdala hyperreactivity
49 to social stimuli [29,30] and we have recently observed increased amygdala responses during

50 social decision-making and social feedback in healthy individuals with high social anxiety [31].

51 By contrast, the neural responsiveness to social rewards such as happy faces seems to be
52 reduced in individuals with social anxiety [31-34], potentially resulting in reduced positive affect
53 in response to social interactions and impaired memory for positive social events [35,36].
54 Similarly, lonely individuals exhibit an attenuated responsiveness to positive social interactions
55 [37] and there is preliminary evidence indicating that alterations in amygdala structure and
56 function are associated with loneliness (for a current comprehensive review of neurobiological
57 factors associated with loneliness, see [38]). However, it is still elusive whether social anxiety
58 and loneliness share similar neurobiological substrates during social interactions or whether
59 psychotherapeutic protocols need to be adjusted to reduce chronic loneliness.

60 The current study therefore aims at examining whether previously reported mechanisms
61 underlying social anxiety (cf. [31]) could be replicated in loneliness. Thus, we recruited a pre-
62 stratified sample of 42 healthy participants scoring high (high-lonely, HL) and 40 control
63 participants scoring low (low-lonely, LL) on a loneliness scale. During functional magnetic
64 resonance imaging (fMRI), the participants completed a social gambling task to measure the
65 subjective value of engaging in a social situation and responses to positive and negative social
66 feedback. The task has been previously used to identify a potential neural circuitry underlying
67 the social avoidance behavior associated with social anxiety (cf. [31]). Given the intertwined
68 phenotype of both constructs, we hypothesized that lonely individuals would exhibit a
69 decreased subjective value of engaging in social situations as observed for social anxiety.
70 Likewise, we expected increased amygdala activation during social decision-making and social
71 feedback and concomitantly decreased reward-associated responses of the nucleus
72 accumbens (NAcc) to positive social feedback in lonely participants. We further tested whether
73 changes in brain activity were associated with altered functional connectivity. In an additional
74 exploratory analysis, we examined distinct behavioral and neural response patterns in
75 loneliness that have not been previously found to be associated with social anxiety (i.e.,
76 responsiveness to negative social feedback). Notably, we controlled for the influence of social

77 anxiety and further potential confounding variables including depressive symptomatology and
78 childhood maltreatment for all observed associations of loneliness with neural or behavioral
79 measurements.

80 **Materials and Methods**

81

82 **Participants**

83 We recruited a sample of 82 (out of a stratified sample of 3678 adults; 41 females, mean age
84 \pm standard deviation (SD): 26.83 ± 7.47 years) pre-stratified healthy volunteers with high ($n =$
85 42) and low loneliness scores ($n = 40$) as assessed by the revised version of the UCLA
86 loneliness scale (UCLA-L, [39]; for details, see supplementary material and [37]). All
87 participants gave written informed consent. The study was approved by the institutional review
88 board of the Medical Faculty of the University of Bonn (study number 016/18) and conducted
89 in accordance with the latest revision of the Declaration of Helsinki.

90

91 **Behavioral tasks**

92 We measured the participants' subjective value of engaging in social situations with a social
93 gambling task (cf. [31] and see supplementary material). During a decision phase, participants
94 could choose a risky (a dice game with a human or computer partner with equiprobable
95 outcomes of 3 or 0 €) or a safe option (a fixed payoff ranging from 0 to 3 €). If participants
96 chose the risky option, either a positive or a negative feedback video of the partner (human or
97 computer) was shown (feedback phase), depending on the outcome of the trial (win or loss).
98 If participants chose the safe option, a sentence confirmed the payoff. Individual certainty
99 equivalents of the risky option (termed CE50), i.e., the certain payoff for which a participant
100 would be indifferent between the risky and safe options (i.e., they would choose each option
101 with equal probability), were estimated separately for the computer and the human partners by
102 fitting participants' choices with a cumulative Gaussian function. CE20 and CE80, i.e., certain
103 payoffs associated with choosing the safe option with 20 % and 80 % probability, were similarly
104 estimated. The subjective value of engaging in social situations was defined as the individual

105 difference between the estimated CE50 for human partners compared to the computer partner.

106 After finishing the task, the pleasantness of each feedback video was rated on a visual
107 analogue scale ranging from 0 (“not pleasant at all”) to 100 (“very pleasant”). The task was
108 then repeated during functional magnetic resonance imaging (fMRI) with randomly chosen
109 partners (human or computer) for each trial. The fixed payoff offered as safe option varied
110 randomly between the individually determined values CE20, CE50, and CE80.

111 We further measured the individual monetary value associated with receiving positive or
112 avoiding negative social feedback during a virtual auction task. Specifically, participants were
113 informed that they were participating in a virtual auction against the computer using a random
114 algorithm to invest money. Participants were then asked with no imposed time limit to invest
115 any amount of money between 0 € and 1 € (in increments of 5 cents) to (1) increase the
116 probability of watching a positive social feedback video or (2) to decrease the probability of
117 watching a negative social feedback video (see supplementary material).

118

119 **Statistical analyses**

120 Behavioral data were analyzed in SPSS 24 (IBM Corp., Armonk, NY) by calculating analyses
121 of variance (ANOVAs) and Bonferroni-corrected (P_{cor}) post-hoc t-tests. P -values < 0.05 (two-
122 tailed) were considered significant. To analyze the fMRI data, we used a two-stage approach
123 as implemented in SPM12 (Wellcome Trust Center for Neuroimaging, London, UK;
124 <http://www.fil.ion.ucl.ac.uk/spm>). On the first level, data were modeled using a fixed-effects
125 model. Within-subject contrasts of interest were entered to a random-effects model on the
126 second level to assess group-specific response patterns by calculating two-sample t-tests.
127 Specifically, to probe the hypothesis of increased amygdala activation during social decision-
128 making in HL participants, we compared brain activity during risky decisions involving a human
129 partner between groups by calculating two-sample t-tests (i.e., HL risky decision human > safe decision human

130 > LL risky decision human > safe decision human, HL risky decision human > risky decision computer > LL risky decision human > risky
131 decision computer). Likewise, the hypothesized increased amygdala responsiveness to social
132 feedback (HL human feedback > computer feedback > LL human feedback > computer feedback) and reduced NAcc
133 reactivity to positive social feedback (LL positive human feedback > positive computer feedback > HL positive human
134 feedback > positive computer feedback) were tested by calculating two-sample t-tests. As the behavioral
135 data indicated an altered responsiveness to negative social feedback (see results), we
136 explored group differences in response to negative human feedback videos (HL negative human
137 feedback > negative computer feedback > LL negative human feedback > negative computer feedback). These contrasts were
138 also calculated in the opposite direction (e.g., LL risky decision human > risky decision computer > HL risky decision
139 human > risky decision computer). The amygdala and NAcc were anatomically defined according to the
140 Wake Forest University PickAtlas [40,41]. *P*-values < 0.05 after familywise error correction for
141 multiple testing (P_{FWE}) were considered significant. Parameter estimates of clusters showing
142 significant group effects were extracted and further analyzed in SPSS 24 to disentangle the
143 group x task condition interaction. Behavioral group effects were correlated with parameter
144 estimates of neural group effects. For details, see supplementary material. The analysis plan
145 was preregistered prior to conducting any analyses (<https://osf.io/x47ke>). All data used in this
146 study are openly available (<https://osf.io/p6jxk/> and
147 <https://neurovault.org/collections/VNYRMORR/>).

148

149 **Explorative analyses**

150 We conducted a multivariate pattern analysis using the Decoding Toolbox [42] to test whether
151 decisions of the participants could be decoded from amygdala activation (cf. [31]). Contrasts
152 revealing significant group effects in the univariate activity analyses (see above) were further
153 examined by generalized psychophysiological interaction (gPPI) analyses using the CONN
154 toolbox 19.b (www.nitrc.org/projects/conn, RRID:SCR_009550). Mediation and moderation
155 analyses were run to examine the potential influence of depressive and social anxiety

156 symptoms (assessed by the Beck's Depression Inventory II, BDI [43] and the Liebowitz Social
157 Anxiety Scale, LSAS [44]) and childhood maltreatment (assessed by the Childhood Trauma
158 Questionnaire, CTQ [45]) on observed loneliness effects. For hypotheses that could not be
159 confirmed, we conducted Bayesian t-tests using JASP [46] to quantify the evidence for an
160 absence of group differences. For details of the explorative analyses, see supplementary
161 material.

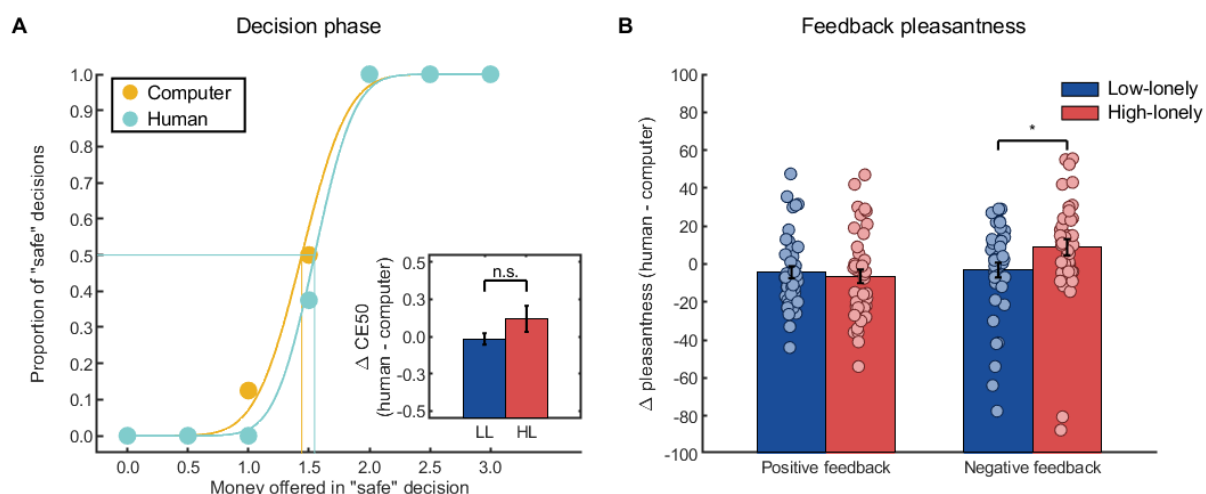

162

163 Results

164

165 Behavioral results

166 As expected, social anxiety was significantly increased in HL participants ($t(67.74) = 3.25, P =$
167 $0.002, d = 0.72$; mean LSAS score \pm SD in HL: 18.64 ± 15.91 ; LL: 9.28 ± 9.56 ; see [37]) and
168 task effects of the social gambling task reported by [31] were replicated across groups (see
169 supplementary material and **Fig. 1A**). However, contrary to previously observed effects of
170 social anxiety [31], loneliness (HL vs. LL) affected neither the subjective value of engaging in
171 social situations during the behavioral social gambling task nor the invested money in the
172 virtual auction task (all P s > 0.05).

173

174 **Fig. 1. Behavioral results of the decision and feedback phase of the social gambling**
175 **task.** (A) The proportion of safe decisions during the social gambling task increased with higher
176 payoffs offered in those safe decisions (main effect of offered payoff for the behavioral task:
177 $F(2.95, 236.14) = 183.77, P < 0.001, \eta_p^2 = 0.70$; functional magnetic resonance imaging task:
178 $F(2, 158) = 185.43, P < 0.001, \eta_p^2 = 0.70$; example data of the behavioral task from one
179 participant with a high loneliness score (HL) are presented). As presented in the inlay, HL
180 participants did not significantly differ from control participants (LL) with regard to the subjective

181 value of engaging in a social situation (i.e., CE50, the payoff offered in the safe option
182 associated with 50% of safe decisions). **(B)** By contrast, groups significantly differed in their
183 pleasantness ratings of the negative feedback videos. Compared to the negative computer
184 feedback video, HL participants rated the negative human feedback video as more pleasant,
185 whereas LL control participants showed the opposite pattern of ratings. No differences
186 between groups were observed for positive feedback. Each marker in (A) represents the mean
187 of 8 trials. Bars represent group means. Error bars indicate standard errors of the mean.
188 Abbreviations: *n.s.*, not significant. * $P < 0.05$.

189

190 Nevertheless, analyses of pleasantness ratings of the feedback videos revealed a significant
191 interaction of group x partner x feedback valence ($F(1,80) = 4.02$, $P = 0.048$, $\eta_p^2 = 0.05$). To
192 disentangle the interaction, we calculated further mixed ANOVAs separately for the positive
193 and negative feedback videos. Surprisingly, no group effects were observed for positive
194 feedback (all P s > 0.05), but HL participants rated the negative human feedback video as more
195 pleasant compared to the negative computer feedback, while LL participants showed the
196 opposite pattern of ratings (interaction of group x partner: $F(1,80) = 4.34$, $P = 0.04$, $\eta_p^2 = 0.05$;
197 see **Fig. 1B**).

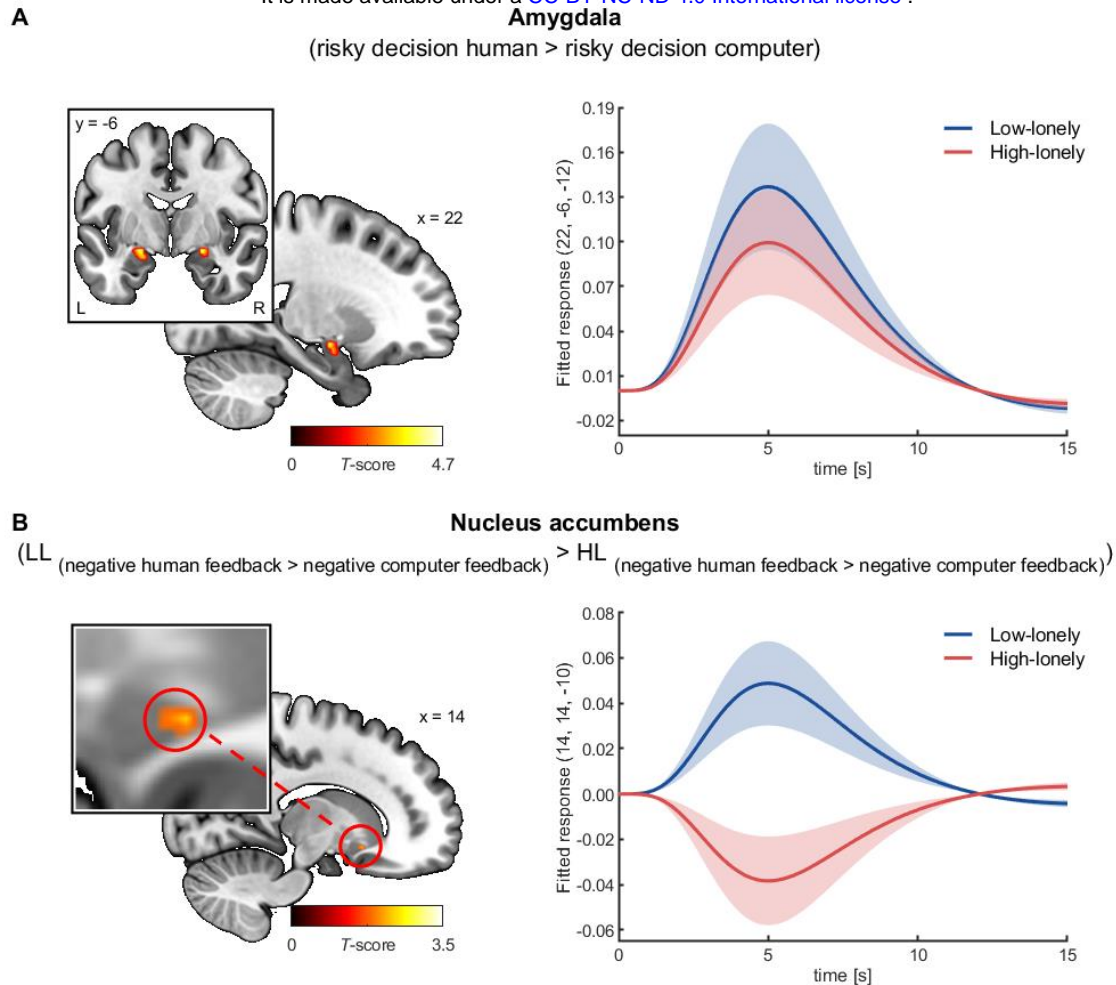

198

199 **fMRI results**

200 Multi- and univariate analyses of neural activation across groups replicated all previous task
201 effects [31]. As such, a linear support vector machine classifier based on amygdala activation
202 was able to decode the decision (risky vs. safe) significantly better than chance (mean
203 accuracy \pm SD = 53.64 ± 9.07 %; 30, -4, ,28, $t(73) = 3.45$, $P_{FWE} = 0.048$). Amygdala activation
204 increased during decisions involving a human partner compared to the computer partner (right:
205 22, -6, -12, $t(73) = 3.68$, $P_{FWE} = 0.03$; left: -22, -8, -12, $t(73) = 4.00$, $P_{FWE} = 0.01$). Specifically,

206 amygdala activity was enhanced during trials in which participants chose the risky option with
207 a human partner compared to the computer partner (right: 22, -6, -12, $t(73) = 4.58$, $P_{FWE} =$
208 0.002; left: -22, -8, -12, $t(73) = 4.23$, $P_{FWE} = 0.006$; see **Fig. 2A**), while no differences in
209 amygdala activity between partners were observed for safe decisions. Moreover, receiving
210 feedback from the human partner activated the amygdala significantly stronger than computer
211 feedback (right: 22, -6, -14, $t(75) = 9.67$, $P_{FWE} < 0.001$, left: -22, -8, -12, $t(75) = 9.66$, $P_{FWE} <$
212 0.001) and NAcc activity across partners was increased in response to positive feedback
213 compared to negative feedback (right: 12, 8, -6, $t(75) = 6.45$, $P_{FWE} < 0.001$, left: -14, 10 -10,
214 $t(75) = 4.91$, $P_{FWE} < 0.001$). See **Table S1** for a comprehensive presentation of whole-brain
215 task effects.

216 Importantly, however, amygdala activation during the decision or feedback stage did not
217 significantly differ between HL and LL participants. Conversely, we observed significant
218 differences in striatal responses to the feedback videos. HL participants showed significantly
219 smaller NAcc responses to human (vs. computer) feedback videos than LL individuals (14, 14,
220 -10, $t(74) = 3.07$, $P_{FWE} = 0.02$). Again, the group difference was specific for negative feedback
221 videos (14, 14, -10, $t(74) = 3.21$, $P_{FWE} = 0.01$; see supplementary material and **Fig. 2B**),
222 whereas no significant group effects were observed for responses to positive feedback videos.
223 Post-hoc tests revealed increased NAcc responsiveness to negative human feedback
224 compared to the computer feedback in LL participants ($t(36) = 2.59$, $P_{cor} = 0.03$, $d = 0.53$),
225 while HL participants exhibited the opposite response pattern ($t(38) = -1.96$, $P_{cor} = 0.12$). No
226 further group differences in brain activity were observed.

227

228 **Fig. 2. Neural activation during the social gambling task. (A)** Amygdala activity was
 229 significantly enhanced during the decision phase of the social gambling task when participants
 230 chose the risky option with a human partner compared to the computer partner (right: 22, -6, -
 231 12, $t(73) = 4.58$, $P_{FWE} = 0.002$; left: -22, -8, -12, $t(73) = 4.23$, $P_{FWE} = 0.006$). In line with the
 232 behavioral results, no group differences in neural activity were observed during the decision
 233 phase. **(B)** During the feedback stage, participants with high loneliness scores (HL) showed
 234 attenuated nucleus accumbens (NAcc) responses to negative feedback given by human
 235 partners compared to the computer partner. In contrast, NAcc reactivity to negative human
 236 feedback was enhanced compared to computer feedback in control participants (LL). Shaded
 237 areas show the standard error of the mean of the fitted responses based on the hemodynamic

238 response function. For illustration purpose, clusters are shown with significance levels of $P <$
239 0.05 uncorrected. Abbreviations: L, left, R, right.

240

241 Exploratory gPPI analyses of the negative feedback condition with the NAcc serving as seed
242 region indicated enhanced functional connectivity of the left NAcc with a cluster including the
243 hippocampus in HL compared to LL participants (-14, -22, -14, $k = 73$, $t(74) = 5.38$, $P_{FWE} =$
244 0.049 on cluster level; see **Fig. 3A**). Again, post-hoc tests revealed an opposing pattern
245 between groups with enhanced connectivity while receiving negative human (vs. computer)
246 feedback in HL participants ($t(38) = 3.06$, $P_{cor} = 0.01$, $d = 0.63$) and reduced connectivity in LL
247 participants ($t(36) = -4.93$, $P_{cor} < 0.001$, $d = -1.15$). Interestingly, NAcc-hippocampus
248 connectivity not only correlated with NAcc responses to negative human feedback (contrasted
249 with negative computer feedback: $r(74) = -0.33$, $P = 0.004$, i.e., increased connectivity was
250 associated with reduced neural reactivity), but also with pleasantness ratings of negative
251 feedback videos ($r(74) = 0.23$, $P = 0.04$, see **Fig. 3B**). The correlation between NAcc activity
252 and negative feedback ratings was similar, but failed to reach significance ($r(74) = -0.20$, $P =$
253 0.09).

255 **Fig. 3. Functional connectivity during the social gambling task.** Participants with high
256 loneliness scores (HL) showed enhanced functional connectivity of the nucleus accumbens

257 (blue sphere) with a cluster including the hippocampus while receiving negative human (vs.
258 computer) feedback compared to control participants (LL). Functional connectivity positively
259 correlated with the pleasantness ratings of the negative human feedback (compared to the
260 negative computer feedback). The dashed line represents the 95%-confidence interval of the
261 plotted regression line. Bars represent group means. Error bars indicate standard errors of the
262 mean. Abbreviations: L, left, R, right. * $P < 0.05$, *** $P < 0.001$.

263

264 **Bayesian analyses and effects of confounding variables**

265 Bayesian analyses revealed moderate evidence for the absence of group differences in
266 variables that have previously been associated with social anxiety (cf. [31]), with our data being
267 at least three times more likely under the null hypothesis (H_0 : no differences between groups)
268 than under the alternative hypothesis (HL differ from LL participants in any direction).
269 Specifically, Bayesian t-tests revealed moderate evidence that HL participants indeed did not
270 differ from LL participants regarding the pleasantness ratings of positive human compared to
271 computer feedback as our data were found to be almost four times more likely under the H_0
272 than under the alternative hypothesis (Bayes factor (BF_{10}) = 0.25, median effect size = 0.08,
273 95 % credible interval: [-0.32, 0.49]). Likewise, Bayesian analyses revealed moderate evidence
274 that groups showed equal reward-associated brain activity in response to positive human
275 feedback (contrasted with positive computer feedback; left NAcc: BF_{10} = 0.25, median effect
276 size = 0.07, 95 % credible interval: [-0.35, 0.49]; for the right NAcc the evidence is inconclusive:
277 BF_{10} = 0.43, median effect size = 0.23, 95 % credible interval: [-0.19, 0.66]) and moderate
278 evidence in favor of the H_0 for amygdala reactivity to human feedback (contrasted with
279 computer feedback; left: BF_{10} = 0.24, median effect size = -0.004, 95 % credible interval: [-
280 0.42, 0.41]; right: BF_{10} = 0.24, median effect size \approx 0.00, 95 % credible interval: [-0.42, 0.42]).
281 The same pattern of results was observed for amygdala activation during the decision stage
282 of the social gambling task as our data were up to four times more likely under the assumption

283 of comparable activation between groups (H_0) than under the alternative hypothesis (left
284 amygdala activation for risky decisions with a human partner compared to a computer partner:
285 $BF_{10} = 0.24$, median effect size = 0.03, 95 % credible interval: [-0.39, 0.45]; left amygdala
286 activation for risky decisions with a human partner contrasted with safe decisions in trials with
287 a human partner: $BF_{10} = 0.33$, median effect size = -0.17, 95 % credible interval: [-0.61, 0.25];
288 right: $BF_{10} = 0.24$, median effect size = -0.01, 95 % credible interval: [-0.43, 0.41]). For right
289 amygdala activation, there was insufficient evidence to draw a conclusion for or against the
290 hypothesis that groups exhibit equal responsiveness to risky decisions involving a human
291 partner (contrasted with the computer; $BF_{10} = 0.50$, median effect size = 0.26, 95 % credible
292 interval: [-0.16, 0.70]). However, descriptive analyses revealed an opposing response pattern
293 in HL participants to what has been expected due to increased social anxiety symptoms. While
294 LL participants showed slightly enhanced amygdala activation (mean parameter estimates \pm
295 SD: 0.25 ± 1.06), amygdala activation was reduced in HL participants (mean parameter
296 estimates \pm SD: -0.02 ± 0.68 ; cf. **Fig. 2A**). Likewise, no evidence for any of the hypotheses
297 (null or alternative hypothesis) was observed for the subjective value of engaging in social
298 situations ($BF_{10} = 0.57$, median effect size = -0.29, 95 % credible interval = [-0.74, 0.15]). Again,
299 descriptive analyses revealed enhanced values of social engagement in HL compared to LL
300 participants, which is contrary to the previously reported negative association with social
301 anxiety (see inlay of **Fig. 1A** and cf. [31]). Regarding the invested money during the virtual
302 auction task, Bayesian analyses provided moderate evidence for comparable investments
303 between groups to avoid negative social feedback ($BF_{10} = 0.33$, median effect size = 0.17, 95
304 % credible interval = [-0.23, 0.59]) or to receive positive social feedback ($BF_{10} = 0.33$, median
305 effect size = 0.18, 95 % credible interval = [-0.23, 0.59]).

306 Mediation and moderation analyses indicated that none of the reported group effects was
307 based on confounding psychiatric symptoms (see supplementary material).

308 **Discussion**

309

310 The current study sought to investigate shared and distinct behavioral and neural response
311 patterns underlying social anxiety and loneliness. Our results revealed that a previously
312 observed neurocircuitry underlying avoidance behavior in social anxiety (cf. [31]) could not be
313 replicated in lonely individuals. HL participants differed from control participants neither in the
314 subjective value of engaging in social situations nor in neural responses to social decision-
315 making and positive social feedback. Conversely, HL participants showed altered
316 responsiveness to negative social feedback evident in opposing behavioral response patterns
317 and striatal brain activity and connectivity compared to control participants.

318 Our results thus indicate that loneliness might be more associated with altered emotional
319 reactivity to social situations than with behavioral tendencies to withdraw from social
320 interactions. Human and animal research have consistently shown that the amygdala is
321 crucially involved in the processing of threat-related stimuli and hyperactivation of the
322 amygdala is known as a core mechanism underlying anxiety disorders [30,47]. Moreover,
323 amygdala habituation to threat-related stimuli and amygdala connectivity with prefrontal
324 regions predict subsequent avoidance behavior [48-50]. Likewise, we have previously found
325 that amygdala activation during decisions in the social gambling task increases with social
326 anxiety symptomatology and negatively correlates with the subjective value to engage in social
327 situations [31]. By contrast, the subjective value of engaging in a social situation did not differ
328 between HL participants and controls and Bayesian analyses revealed evidence for
329 comparable amygdala activation during the decision and feedback stages. In line with our
330 findings, neuroanatomical correlates of social avoidance behavior were previously found to be
331 unaffected by loneliness [51]. This notion is consistent with etiological theories that highlight
332 maladaptive social cognitions in the development and maintenance of loneliness [27,52].
333 Likewise, cognitive-behavioral interventions were found to be more effective in targeting social

334 biases than social skill trainings [53,54]. There is preliminary evidence that established
335 cognitive-behavioral treatments targeting social anxiety concurrently decrease feelings of
336 loneliness and vice versa [55-59], but our findings of distinct behavioral and neural substrates
337 suggest that loneliness-adjusted protocols might improve therapeutic outcomes.

338 Moreover, our results provide new insights into the neural pathways underlying loneliness.
339 Unexpectedly, striatal activity during negative social feedback was reduced while pleasantness
340 ratings were increased in HL participants. Notably, activation of the NAcc is associated with
341 goal-directed approach and avoidance behavior and involved in avoiding social punishment
342 [60-62]. As HL participants rated the negative social feedback videos as more pleasant than
343 the control participants, reduced NAcc responses to negative social feedback might thus reflect
344 reduced tendencies to avoid this negative social feedback. Furthermore, the enhanced
345 functional coupling of the NAcc with a hippocampal cluster that correlated with individual
346 pleasantness ratings is in line with the involvement of this neural circuit in hedonic processing
347 [63] and might reflect the rewarding experience of a social feedback for socially deprived
348 individuals [64]. Nevertheless, we have recently found a compromised neural integration of
349 social information in HL participants evident in various brain regions including the NAcc [37].
350 Furthermore, loneliness has been associated with a reduced recognition of negative vocal
351 expressions [65]. Thus, the reduced NAcc activity might also reflect diminished differentiation
352 between positive and negative feedback, resulting in a dysregulated reward system
353 responsiveness to negative social stimuli as observed for the NAcc-hippocampus connectivity.
354 However, inference about cognitive processes from neural activation should always be drawn
355 with restraint [66] and results regarding biased emotion recognition in loneliness are
356 inconclusive [67]. Future studies are warranted to further investigate the impact of loneliness
357 on the processing of negative social feedback.

358 Interestingly, differences between HL and control participants were restricted to behavioral and
359 neural responses to negative social feedback, whereas Bayesian analyses revealed evidence

360 for a comparable responsiveness to positive social feedback between groups. Conversely,
361 social anxiety has been consistently found to affect the processing of social rewards [31-34].
362 Previous studies point to various negative effects of loneliness on the processing of positive
363 social interactions [37,68,69], but findings about the association between loneliness and NAcc
364 reactivity to positive social stimuli are mixed. The involvement of the NAcc in loneliness might
365 be context-dependent, with feelings of social isolation promoting the hedonic experience of
366 positive social stimuli in an acute stage [64], which may be different from chronic loneliness.
367 Similarly, lonely individuals might experience a social stimulus as more rewarding only if the
368 stimulus is already familiar (e.g. a romantic partner and not a stranger [70]). Along these lines,
369 a recent study found no relationship of loneliness with striatal responsiveness to pictures
370 depicting strangers during positive social interactions [71]. Nevertheless, in our task design
371 positive feedback was always coupled with monetary gains. Thus, differences regarding
372 positive social feedback might have been obfuscated by the rewarding experience of earning
373 money as evident in enhanced striatal responsiveness to positive feedback, irrespective of the
374 partner providing the feedback. Both external (e.g., passive viewing of positive social
375 interactions vs. being involved in a positive social interaction) and internal factors (e.g., state
376 vs. chronic feelings of social isolation) may influence the association of loneliness with social
377 reward processing.

378 Moreover, given the quasi-experimental, cross-sectional design of our study, our findings do
379 not allow casual inferences about the relationship of loneliness and social feedback
380 processing. In addition, moderation and mediation analyses indicate that the observed
381 associations with loneliness were not driven by psychiatric symptoms that were also more
382 pronounced in HL individuals. However, our study specifically focused on high-lonely healthy
383 individuals who may represent a resilient subsample of the population because they did not
384 develop acute psychiatric disorders. Thus, clinical studies with psychiatric patients are
385 warranted to uncover the direction of the observed associative relationships and to further
386 disentangle shared and distinct mechanisms underlying loneliness and psychopathology.

387 Collectively, the current results suggest that loneliness and social anxiety are distinct
388 constructs with specific behavioral and neural substrates. Along these lines, interventions
389 targeting loneliness-specific cognitive biases may be more effective in reducing loneliness than
390 cognitive behavioral therapies focused on reducing avoidance behavior.
