20 **Abstract—word count (150 words max)**

21 We used a noninvasive electrochemical quantitative assay for IgG antibodies to SARS-
22 CoV-2 S1 in saliva to investigate the kinetics of antibody response in a community-based
23 population who had received either the Pfizer or Moderna mRNA-based vaccines. Samples were
24 received from a total of 97 individuals including a subset of 42 individuals who collected
25 samples twice-weekly for 3 months or longer. In all, 840 samples were collected and analyzed.
26 In all individuals, salivary antibody levels rose sharply in the 2-week period following their
27 second vaccination, with peak antibody levels being at 10-20 days post-vaccination. We
28 observed that 20%, 10% and 2.4% of individuals providing serial samples had a 90%, 95%, and
29 99% drop respectively from peak levels during the duration of monitoring and two patients fell
30 to pre-vaccination levels (5%). The use of non-invasive quantitative salivary antibody
31 measurement can allow widespread, cost-effective monitoring of vaccine response.

32

33

34

INTRODUCTION

35 The pandemic caused by SARS-CoV-2 has led to worldwide fatalities and social and
36 economic disruption. In the autumn of 2020, the FDA issued emergency use authorization for
37 two mRNA-based vaccines manufactured by Pfizer/BioNTech COMIRNATY® (Pfizer) or
38 Moderna/NIAID (Moderna). Both vaccines use mRNA sequences from the S1 domain of the
39 SARS-CoV-2 Spike Protein (*1-5*), and vaccines require two doses given 21 or 28 days apart in
40 order to achieve 95% protection against SARS-CoV-2 infection (*1-5*). It is unclear whether all
41 individuals developed antibodies with 5% at risk of breakthrough infection, or whether a modest
42 fraction of individuals will not respond develop antibodies and remain at risk of infections.

43 Unlike the predicted statistics for the healthy general population, it is known that patients
44 on immunosuppressive drugs and cancer patients may not develop a robust antibody response to
45 vaccine administration (*7*). It is possible that a fraction of individuals in the population may have
46 an undetected immune deficiency that prevents them from responding appropriately to the
47 standard vaccine regimen. Consequently, the Centers for Disease Control and Prevention (CDC)
48 is currently recommending booster immunizations be deployed beginning in the fall of 2021(*8*).

49 Several studies have demonstrated that circulating antibody levels decrease over time
50 following either vaccination or infection (*9-14*). Breakthrough infections are being observed in
51 fully vaccinated individuals. It is not known what level, if any, of circulating antibody is
52 required to have immunoprotection against COVID-19 infection. Current publications report
53 very little information regarding the kinetics of antibody levels in patients following vaccination
54 and these studies only report antibody levels at 5.5 weeks and 90 day intervals post second
55 vaccination respectively (*15,16*). Current research is underway to determine whether the efficacy
56 of booster immunization doses and its timing in protecting against SARS-CoV-2 infection,

57 especially in light of the emergence of highly contagious variants such as the delta variant that
58 may be less sensitive to the current vaccines.

59 It is clear that most, if not all, individuals receiving both doses of either the Pfizer or
60 Moderna vaccine respond with a robust IgG response (1-5). However, what is lacking, is
61 frequent kinetic monitoring and long-term monitoring of antibody levels in a community
62 vaccinated population. Non-invasive monitoring using saliva allows for frequent and long-term
63 monitoring of vaccinated individuals and entire populations.

64 We have developed a saliva-based quantitative assay for IgG antibodies to the S1 domain
65 of Spike protein in SARS-CoV-2 using a novel electrochemical platform formerly known as
66 EFIRM® and now called Amperial® (17). Previously, we used this assay to monitor patients
67 who had recovered from COVID-19. This assay was greater than 98% specific for individuals
68 with prior COVID-19 infections and gave proportional results to serum assays performed at the
69 same time on the same patient. Two other groups have similarly demonstrated the ability of
70 saliva to be a surrogate for serum or plasma measurement of SARS-CoV-2 antibodies (18,19).

71 **METHOD**

72 **SARS-CoV-2 Salivary Assay Equipment**

73 The Amperial® platform uses a proprietary 96-well microtiter plate containing gold
74 electrodes at the bottom of each well and an electrochemical reader system (EZLife Bio Inc, Los
75 Angeles, CA). The description of the Elzie Amperial® COVID-19 Antibody assay and the assay
76 performance and validation have been described previously (17) and is summarized in the
77 following section.

78 **Immobilization of SARS-CoV-2 on Plate Surface**

79 For the preparation of the antigen coated wells we prepare a 10 µg/mL SARS-CoV-2 S1
80 antigen (SinoBiological US Inc, Wayne, PA) diluted in a solution of 72.25 mM pyrrole (Sigma-
81 Aldrich, St. Louis, MO) and 0.147M KCl mixture. This antigen-polymer mixture was then
82 briefly vortexed for 1 sec and then 30 µL was added to each well. Each plate contains wells
83 containing antigen alternated with wells containing polymer without antigen added. The plate
84 was then inserted into the electrochemical plate device and a square wave potential applied that
85 consists of 1 second of +350 mV and 1 second for +1100mV for 4 cycles (8 seconds total) to
86 electropolymerize the polymer and antigen-polymer on the surface. After the electrochemical
87 polymerization, each electrode was washed for 3 cycles in a buffer of 1x phosphate-buffered
88 saline (PBS, Affymetrix, USA) and 0.05% Tween 20 (BioRad, USA), referred to as PBS-T.

89 **Sample Preparation and Incubation**

90 Saliva samples were diluted 1:10 in a 1% (w/v) Casein/PBS solution (ThermoFisher,
91 Waltham, MA). Internal standards consist of SARS-CoV-2 IgG antibodies (Absolute Antibody,
92 Oxford, United Kingdom) diluted in 1% (w/v) Casein/PBS solution at varying concentrations in
93 the linear range of the assay to provide a standard curve. Thirty microliters of the samples and
94 standard are then added to their respective wells in the coated electrode plate. All patient samples
95 were added to both a pyrrole only well and an S1 antigen coated well. The plate is incubated at
96 room temperature for 10 min before washing with PBS-T.

97 **Secondary Antibody and Reporter Enzyme**

98 Subsequently biotinylated Goat Anti-Human IgG Fc (ThermoFisher, Waltham, MA) was
99 diluted 1:500 in 1% (w/v) Casein/PBS solution and 30 μ L added to the well. The plate was then
100 incubated for 10 min at room temperature before a PBS-T wash.

101 Following the removal of the secondary antibody, a Poly80 Horseradish peroxidase
102 enzyme is prepared at 1:5 dilution ratio in 1% (w/v) Casein/PBS solution and incubated at 10
103 minutes at room temperature prior to another PBS-T wash.

104 **Measurement of Electrochemical Signal and Data Analysis**

105 Sixty microliters of 1 Step Ultra-TMB (ThermoFisher, Waltham, MA) is added to the
106 wells and the plate immediately inserted into the electrochemical reader device, with a fixed
107 potential of -200 mV and simultaneous measurement of electrochemical current for all 96 wells
108 is measured 2 separate times over a 60 second period.

109 Signal of the last 10 seconds of the readout procedure is averaged for final quantitative
110 signal value. All saliva samples tested were normalized by subtracting the signal of the polymer
111 only wells with the antigen-polymer coated wells. Standards were also compared to calibrators
112 for quantification.

113 **Human Subjects**

114 Research protocol and consents were approved by the Western Internal Review Board
115 (Study #1302611, Expiration Date: March 19th, 2022).

116 Individuals under the age of 18 years and individuals receiving immunosuppressive drugs or
117 cancer chemotherapy were excluded from the study.

118 Volunteers who had previously received a Pfizer (BioNTech), Moderna, or Johnson and
119 Johnson Vaccine for SARS-CoV-2 were consented. Subjects were issued a questionnaire
120 collecting information about vaccination dates and vaccine type, along with questions to
121 eliminate subjects who were immunocompromised or taking immunosuppressants.

122 The study comprised of a longitudinal and a cross-sectional study cohort. For the
123 longitudinal study cohort, a cohort receiving either the Pfizer (n=15) or Moderna (n=27) mRNA
124 vaccine were monitored with a first-morning twice-weekly collection. Collections lasted for as
125 long 8 months post vaccination for some individuals. We analyzed saliva at a single time point
126 for another 31 and 24 individuals receiving the Pfizer and Moderna vaccines respectively. This
127 has allowed us to make several conclusions regarding the kinetics of COVID-19 vaccine
128 response in community vaccinated populations. In all more than 840 samples have been collected
129 and analyzed.

130 **Sample Processing Device and Protocol**

131 Saliva samples were collected using the Orasure® Oral Fluid Collection Device (Orasure
132 Technologies, Bethlehem, PA), which consists of an absorbent pad on the end of a long wand
133 and a collection tube with preservative solution. Subjects insert the absorbent pad in the mouth
134 for a minimum of 2 minutes in order to absorb adequate saliva fluids. The absorbent pad is then
135 immersed into a collection tube and the wand broken at a scored breakpoint to allow the device
136 to be securely capped. Individuals participating in longitudinal studies placed the capped
137 collectors in a zip lock bag and then into their home freezer until shipping them to the laboratory
138 at ambient temperature. Individuals providing single samples kept the samples at room
139 temperature until shipping to the laboratory.

140 Upon receipt at a central laboratory, the tube is uncapped, the pad gently pressed on the
141 inside of the tube to squeeze out saliva, and the saliva transferred into a labeled microcentrifuge
142 tube for testing. Samples are stored at -80C for long term storage. Previous evaluations of the
143 collection system (17) have demonstrated the system can store the samples at room temperature
144 for greater than 10 days without significant degradation in antibody levels.

145 **Variant Antigen (Delta)**

146 To determine whether the antibodies of vaccinated or convalescent patients were reactive
147 to the delta variant, we used SARS-CoV-2 variant S1 Antigen B.1.6.617.2 (40591-V08H23
148 SinoBiological, Wayne, PA), a recombinant antigen that included T194, G142D, E156G, 157-
149 158 deletion, and the L452R, T478K, D614G, 681R mutations. Identical amounts of this variant
150 antigen are immobilized in the gel and the standard assay is performed.

151 **RESULTS**

152 **Kinetic Studies**

153 We analyzed 42 vaccinated patients (27 Moderna, 15 Pfizer) who provided
154 twice-weekly samples for a period of several weeks. The general patterns for all patients were
155 comparable to one another. Figure 1 demonstrates 8 representative samples from this
156 longitudinal. The curves are oriented with zero time being the date of the second injection. The
157 general patterns are similar for individuals receiving both vaccines with a spike in antibody
158 production 1-2 weeks following the second injection followed by a steady decrease in antibody
159 levels. There were, however, differences in the robustness of response, with most volunteers
160 having robust responses with 100 ng / mL – 200 ng / mL of IgG as a peak response followed by
161 a gradual decrease in levels over time.

162 As can be seen in Fig 1, however, 2 individuals responded with a maximum level of 50
163 ng / ml. Individual 3 in the Pfizer group had a peak response of approximately 50 ng / ml and
164 then stabilized at approximately 25 ng / ml. Individual 3 in the Moderna group had a short-
165 duration peak of 50 ng /ml followed by a return to baseline 30 days post second vaccination. All
166 but 2 patients experienced a gradual, but steady decline in antibody levels. These decreasing
167 levels may correlate with the need for booster vaccinations.

168 Clinical trials data revealed an approximate 50% protection for individuals 2 weeks after
169 having received their first immunization with either the Modern or Pfizer vaccine (1-5). We
170 wondered whether this could be a function of antibody response in vaccinated patients. Of the 42
171 subjects that were serially monitored, 36 supplied samples before the second dose. In the subjects
172 that were collected prior to the second dose, 88% of the Moderna subjects had detectable
173 antibodies prior to the second dose and 50% of the Pfizer subjects had detectable antibodies prior
174 to the second dose (see Table 2).

175 **Summary Statistics for Kinetic Studies**

176 Table 1 shows the summary statistics for the volunteers participating in the kinetic
177 studies. The average time to maximum antibody level was 22 days for Moderna and 30 days for
178 Pfizer. The maximum levels were nearly identical for the 2 vaccines with Moderna vaccinated
179 individuals having average peak levels of 127 ng / ml and 130 ng /ml respectively for Moderna
180 vaccinated and Pfizer vaccinated individuals. These levels are similar to those we observed in
181 convalescent hospitalized COVID-19 patients and 5 fold higher than more mildly symptomatic
182 individuals (17).

183 In addition to the 42 volunteers participating in the kinetic studies we had an additional
184 53 individuals submitted single samples for this study. Figure 2 is a summary of all the data

185 representing 840 individual time points including the multiple time points for the 42 volunteers
186 submitting multiple samples and the 53 volunteers submitting only one samples. The samples are
187 normalized to days after receiving the second vaccine dose.

188 Figure 2 is a summary of these data showing a box plot of weekly antibody levels for
189 individuals both pre and post second vaccination. The trend is clear. Robust antibody levels are
190 present for the initial 60 days following the second vaccination. Subsequently, levels begin
191 falling gradually, but consistently. The data demonstrate a steady decrease in antibody levels
192 with increasing time following vaccination.

193 **Summary of subjects with significant drops from peak value**

194 Table 3 is a summary of volunteers who have experienced drops of more than 90%, 95%,
195 and 99% from their peak values grouped by vaccine type. Although a higher percentage of Pfizer
196 vaccinated patients experience a decrease of 90% or more (33% vs 15%) and 95% or more (13%
197 v 8%) no Pfizer volunteers experienced a 99% drop whereas one Moderna vaccinated patient
198 experienced a 99% drop in antibody levels (see Table 3). The numbers are not sufficient to form
199 any conclusions regarding any potential differences between the 2 vaccines but do show that,
200 with time, antibody levels drop to 90% of their peak level in 20% of community vaccinated
201 individuals.

202 Figure 3 are the kinetic plots of the 9 vaccinated individuals who experienced >90%
203 drops in antibody levels following vaccination. It is apparent that that there is no correlation with
204 the original peak value with prediction of eventual 90% drop in antibody level. Two individuals
205 had peak levels above 200 ng / ml indicating a robust initial response. There were two volunteers
206 who had initial peak values of only 50 ng / ml who also dropped to low levels. Two individuals
207 (5%) dropped to undetectable levels; one a Pfizer patient and one a Moderna patient.

208 **Case Study: Prednisone Effects**

209 A male patient in their sixties was given a 3 week course of prednisone (50 mg / day for
210 14 days followed by a week of tapering) for a nasal polyp approximately 2 months after his
211 second dose of vaccine. The kinetics of his antibody production is shown in Figure 4 with the
212 time period that the prednisone was being administered is highlighted in grey. As can be seen,
213 antibody levels began falling with the onset of treatment to baseline levels and remained
214 suppressed for several weeks following the taper. However, antibody levels did rebound and then
215 began to slowly decline thereafter.

216 **Evaluation of Delta Variant Antigen to Salivary Antibodies**

217 The Delta variant of SARS-CoV-2 has become the predominant variant in the United
218 States. We therefore investigated whether antibodies present in convalescent and vaccinated
219 patients are capable of recognizing the S1 antigen of the Delta variant. We designed an
220 Amperial® assay substituting monoclonal S1 delta variant antigen for the wild type S1 antigen
221 (see Methods). The standard curves for this assay compared to the wild type antigen assay are
222 shown in Figure 5A and demonstrate very similar assay characteristics. There is some indication
223 of slightly reduced binding efficiency for monoclonal Anti-S1 antibodies to the Delta variant
224 versus the wild type S1 antigen but these differences are not enough to alter testing results.

225 Next, we investigated whether antibodies present in convalescent individuals and
226 vaccinated individuals could recognize and bind to the Delta variant S1 antigen. A total of 3 pre
227 2019 samples were used as controls, with also 1 immunodeficient organ transplant patient run for
228 reference. Three samples from convalescent patients with detectable antibody levels were used.
229 These patients were infected before the delta variant emerged. In addition, 3 Pfizer and 4

230 Moderna vaccinated individuals with detectable antibody were analyzed in parallel by both the
231 Wild Type assay and the Delta Amperial® assay.

232 These data are shown in Figure 5B. For all cases of vaccinated and convalescent subjects
233 there was no significant reduction of apparent antibody concentration in saliva to the Delta
234 variant versus the Wild Type. These data demonstrate that antibodies made against the current
235 Moderna and Pfizer vaccines do recognize the S1 domain of Delta variant Spike Protein. In
236 addition, individuals infected prior to the emergence of the Delta variant Convalescent also
237 developed antibodies that recognize the Delta variant. Although this cannot insure an equal
238 protection level against serious infection, it is reassuring.

239 DISCUSSION

240 This study demonstrates that, although all individuals vaccinated with Pfizer or Moderna
241 vaccine develop a robust antibody response, the response wanes over time. Approximately 20%
242 of vaccinated individuals experience a drop off of >90% after 90 days post vaccination. In 2
243 (5%) of serially monitored patients, antibody levels became undetectable. The ability to monitor
244 vaccine response non-invasively can be an important way to identify individuals who may
245 require additional injections without straining stretched health care resources.

246 Although some individual variability is seen among individuals in terms of fluctuating
247 levels, it is easy to determine trends over time using serial saliva monitoring. Previous studies
248 have determined that serum and saliva levels are highly correlated (17-19). However, one cannot
249 predict the absolute serum level by measuring the salivary level. It appears that each individual
250 has his or her own gradient between saliva and serum. However, as the data in the article
251 demonstrate, that gradient remains relatively constant over time allowing longitudinal
252 monitoring to be performed.

253 Herd immunity from widespread community vaccination is a key component in
254 preventing COVID-19 infections and in curbing the pandemic. Several questions remain
255 unanswered. Our data can help provide the answers to some of these questions:

256 Does everyone respond to vaccination with a robust immune response? In this study all
257 vaccinated individuals did respond, although some with much lower antibody levels than the
258 average. Antibody monitoring post vaccination could identify the individuals who did not react
259 to vaccination with a robust antibody response and allow these individuals to have an
260 immunologic evaluation or an additional injection or a different vaccine type.

261 Will booster vaccination be necessary? Recent data regarding breakthrough infections
262 and CDC recommendations are for immunocompromised individual and patients receiving
263 immunosuppressive therapy should receive a third dose of the vaccine regardless of timing.
264 Health care workers and high-risk individuals are scheduled to receive boosters in September.
265 Our data supports this approach in that most individuals experience a continuous drop in
266 antibody levels with time and 5% of individuals dropped to undetectable levels. Although it is
267 not clear what level of antibody, if any, is necessary to prevent COVID-19 infection, individuals
268 with baseline levels of antibodies may be at higher risk to acquire infection.

269 Will a fourth vaccination be needed? Future kinetic studies will be necessary to
270 determine if antibody levels will remain stable following a third vaccination. Noninvasive
271 monitoring using saliva home collection provides a low cost, effective way to perform
272 population monitoring of vaccine levels following a third vaccination.

273 Will the current vaccines protect against the Delta variant? Our data shows that
274 antibodies produced in convalescent patients or mRNA vaccinated subjects do recognize the

275 Delta variant. Although this cannot insure an equal protection level against serious infection it is
276 reassuring.

277 Could any individuals in low-risk groups benefit from booster vaccination? Our data
278 suggests that about 20% of individuals experience a fall of >90% of antibody levels 3 months
279 following completion of their vaccination protocol. These individuals might benefit from early
280 booster shots to prevent breakthrough infections. If an individual with a low antibody level is
281 identified by saliva testing, further evaluation can be performed using serum titers to confirm the
282 initial observation.

283 We should stress that it has not been determined what level of circulating IgG antibody, if
284 any, is necessary to prevent COVID infection. The data in this article must be interpreted in that
285 light. The ability to noninvasively and cost efficiently quantitates COVID-19 antibody levels
286 could be an important tool in investigating the relationship between circulating antibodies to
287 immunity.

288 The results presented in this work regarding the salivary monitoring of SARS-CoV-2 are
289 congruent with recommendations given by the USA CDC and established literature regarding
290 SARS-CoV-2 antibody in vaccinated populations. While there still remains a need for a more
291 comprehensive evaluation of the relationship between salivary SARS-CoV-2 antibodies and
292 those present in the blood, our work demonstrates that our noninvasive quantitative saliva assay
293 could be valuable for evaluating a community vaccinated population and to further investigate
294 the relationship between circulating antibody to COVID-19 immunity.

386

387 Table 1: Summary Statistics for kinetic studies on vaccinated volunteers

	Moderna	Pfizer	Combined
Total Subjects for Longitudinal Study	27	15	42
Average Time Post 2nd Dose to Max Ab	22 days	30 days	24 days
Average Maximum Antibody Level	127 ng / ml	124 ng / ml	126 ng / ml

388

389

390

391

392

393 Table 2. Summary of subjects with measurable antibodies prior to completion of second dose

	Moderna	Pfizer	Combined
Individuals With Data Collected Prior to 2nd Dose	26	10	36
Antibody Produced Before 2nd Dose	23 (88%)	5 (50%)	28 (77%)

394

395

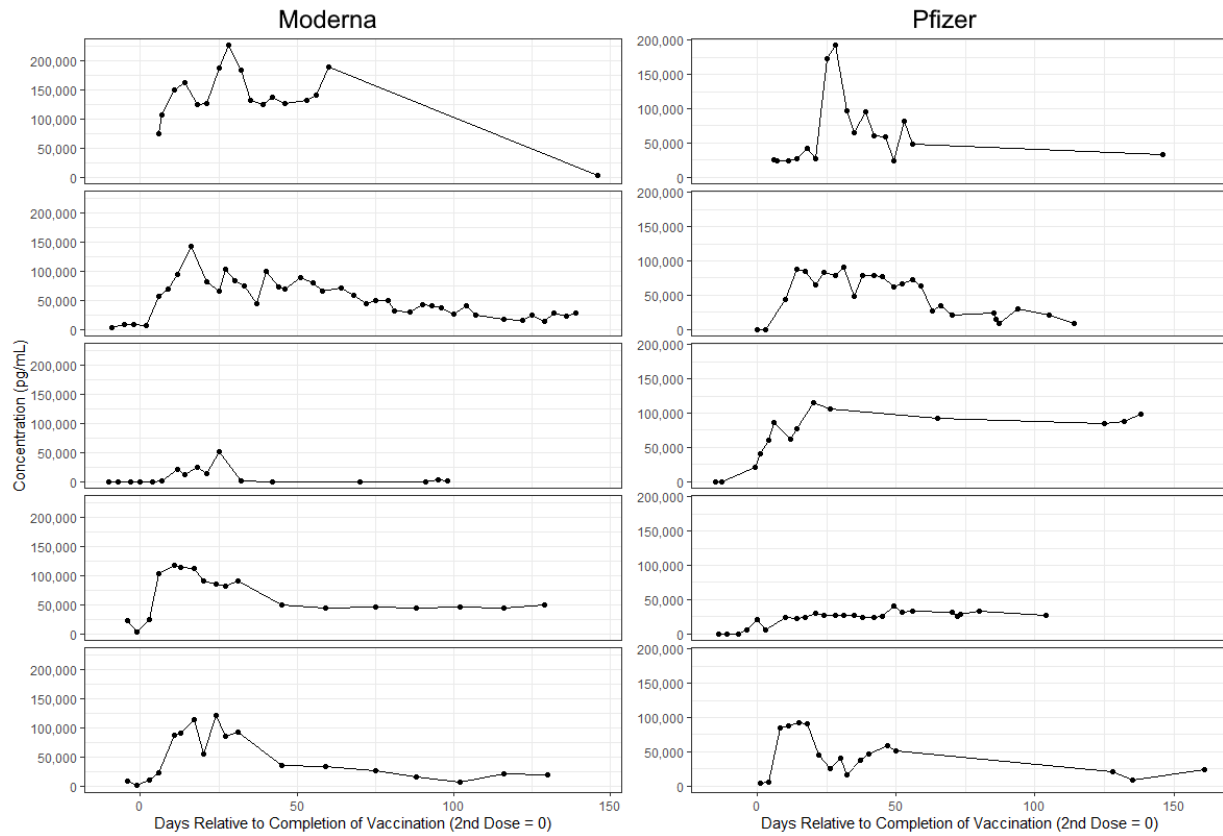

396 Table 3: Individuals with large drops in antibody levels

	Moderna	Pfizer	Combined
Subjects with $\geq 90\%$ drop	15% (4/27)	33% (5/15)	19% (8/42)
Subjects with $\geq 95\%$ drop	8% (2/27)	13% (2/15)	10% (4/42)
Subjects with $\geq 99\%$ drop	4 % (1/27)	0% (0/15)	2.4% (1/42)

397

398

399 Figure 1. Representative Individual Kinetic Experiments: Pfizer and Moderna, with graphs
400 centered around time 0 being the day of the second vaccination.

401

402

403

404

405 Figure 2. Samples collected from volunteer subjects (n=99) at different time intervals for Pfizer
406 (n=47) and Moderna (n=52) vaccines were tested and binned to different time intervals relative
407 to completion of second dose of mRNA vaccine.

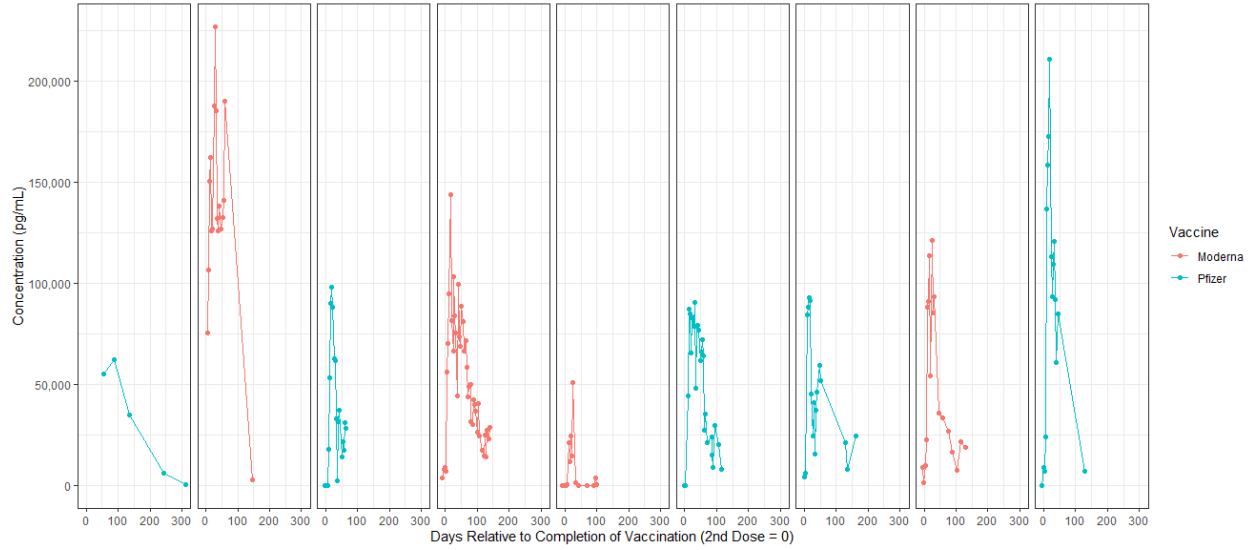

408

409

410

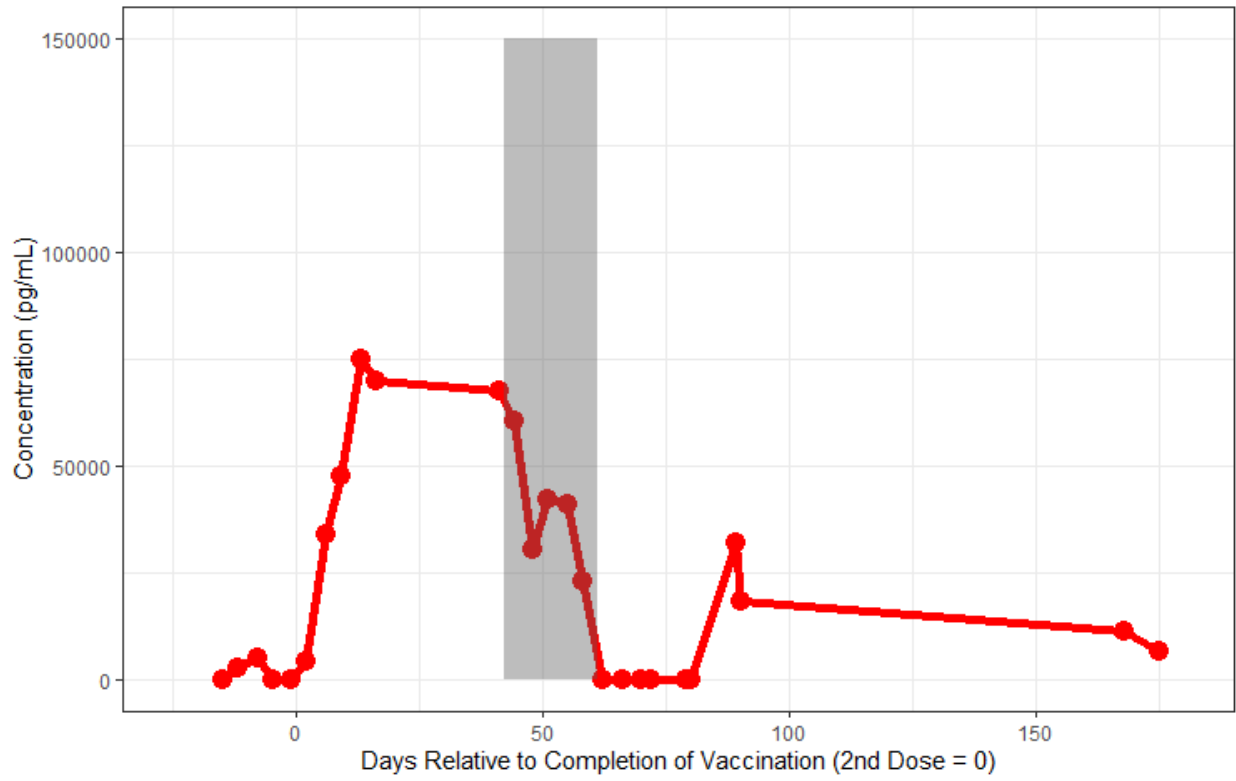

411 Figure 3. Plot of individuals measured with over 90% drop from peak.

412

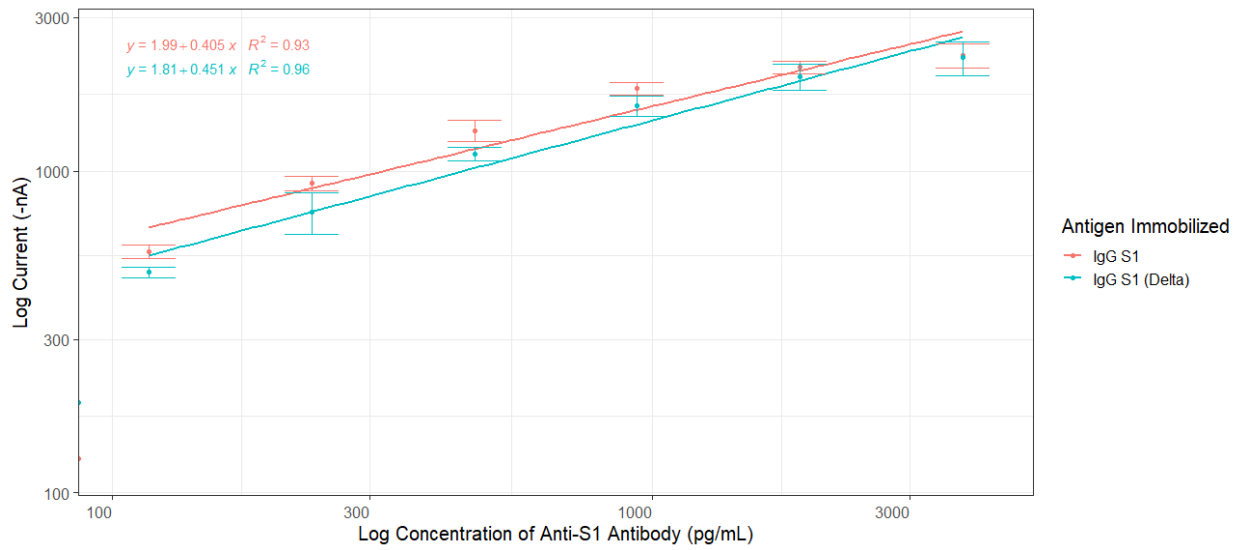

413

414 Figure 4. Case Study Plot of Pfizer vaccinated individual who was administered prednisone
415 following his vaccination. Shaded area of grey indicates the period of time where prednisone was
416 taken.

417

418 Figure 5A: Standard curves for both the Wild type and Delta Variant S1 antigens

420 Figure 5B: Comparison of Wildtype Anti SARS-CoV-2 IgG S1 and B.1.6.617.2 variant S1

421 SARS-CoV-2 antigen

Moderna

Days Relative to Completion of Vaccination (2nd Dose = 0)

Pfizer

Days Relative to Completion of Vaccination (2nd Dose = 0)
