Abstract

1

2 **Background:** Paradoxically, *Helicobacter pylori*-positive (HP⁺) advanced gastric cancer patients have a better prognosis than those who are HP-negative (HP-). Immunologic and 3 4 statistical analyses can be used to verify whether systematic mechanisms modulated by HP are involved in this more favorable outcome. Methods: A total of 658 advanced 5 gastric cancer patients who underwent gastrectomy were enrolled. HP infection, 6 7 mismatch repair, programmed death-ligand 1 (PD-L1), and CD4/CD8 proteins, and microsatellite instability were analyzed. Overall survival (OS) and relapse free survival 8 9 (RFS) rates were analyzed after stratifying clinicopathological factors. Cox proportional 10 hazards regression analysis was performed to identify independent prognostic factors. 11 **Results:** Among 491 cases that were analyzed, 175 (36%) and 316 (64%) cases were HP⁺ 12 and HP⁻, respectively. Analysis of RFS indicated an interaction of HP status among the subgroups for S-1 Dose (P=0.0487) and PD-L1 (P=0.016). HP⁺ patients in the PD-L1 13 14 group had significantly higher five-year OS and RFS than HP patients (81% vs. 68%; P=0.0011; HR 0.477; and 76% vs. 63%; P=0.0011; HR 0.508, respectively). The five-15 16 year OS and RFS was also significantly higher for HP⁺ compared to HP⁻ patients in the 17 PD-L1 $^{-1}$ S-1-reduced group (86% vs. 46%; p=0.0014; HR 0.205; 83% vs. 34%; p=0.001; 18 HR 0.190, respectively). Thus, HP status was identified as one of the most potentially

Koizumi et al -4-

- important independent factors to predict prolonged survival. Conclusion: Modulation of 1
- host immune system function by HP may contribute to prolonged survival in the absence 2
- 3 of immune escape mechanisms of gastric cancer.

Koizumi et al -5-

Introduction

1

2 Gastric cancer (GC) is the third most frequent cause of cancer death worldwide (1, 2). In Japan, the five-year overall survival (OS) for early GC exceeds 95%, but that for 3 4 advanced GC is only between 40 and 70% (3-5). S-1 post-operative adjuvant chemotherapy provides a significant survival improvement for Stage II/III GCs, based on 5 results of a series of clinical trials (6-8). In daily practice, the five-year recurrence rate 6 after curative gastrectomy for Stage II/III GCs remains between 20 and 40% (9). Although 7 8 there still is no gold standard molecular marker for advanced GC patient treatment 9 stratification, previous studies, including ours, demonstrated that HP⁺ advanced GC 10 patients have a better survival rate than HP patients (10-14). Interestingly, similar observations have been reported from various regions around the world including Taiwan, 11 12 Germany, the United States, Korea, and Japan (10-14). Advanced GC patients in these regions are likely to have received different treatments, and to be of different ethnic 13 14 groups and races, in addition to being infected with different HP strains. In fact, the HP 15 genotype cagA, is largely divided into Western and East Asian groups based on genetic 16 polymorphisms of EPIYA motifs coded by the SHP-2 domain of cagA (15). This 17 frequently found polymorphism in East Asian strains is suggested to be associated with a 18 high risk of gastric carcinogenesis (16). However, most studies on HP in the context GC

Koizumi et al -6-

havefocused on carcinogenesis or early-stage cancers. The aforementioned series of previous reports suggest that HP infection may have a specific impact on treatment efficacy or anti-tumor mechanism in advanced GC patients. We reported for Japanese patients with advanced GC, five-year OS rate of 77% and 69% for HP⁺ than HP⁻ patients, respectively (13). HP infection can be a risk factor of GC development from intact gastric mucosae, but the effect of HP infection after GC progression and its functional effect on advanced GC treatment efficacy is unclear (17). Importantly, the large majority (>97%) of people infected with HP never develop GC (18). If HP infection functionally affects GC progression and treatment, understanding the mechanism of the effects would be informative for the majority of the HP⁺ population. HP infection in the gastric mucosa activates an innate immune response that is followed by cell-mediated and humoral immunity of the host (19, 20). At a molecular level, HP infection triggers injection of CagA protein into gastric mucosal cells, which eventually promotes cellular protein degradation (21). Although HP infection processes are thought to result in DNA damage, that may arise following HP-dependent downregulation of mismatch repair (MMR) gene expression (22, 23). MMR protein levels are reported to increase in response to HP infection, suggesting that MMR protein levels could parallel the degree of DNA damage (24). In addition, GC patients showing

Koizumi et al -7-

1 MSI, a hallmark genotype of DNA damage repair deficiency, have a better prognosis than

those having a microsatellite stable (MSS) genotype (25, 26). Interestingly, an association

between HP⁺/PD-L1⁺ and MSI in GC patients suggests a possible link between HP

infection and PD-L1 expression (27-29).

In the present study, we sought to clarify whether systematic function induced

by sustained HP infection may be involved in prolonged survival of patients with

advanced GC. Analyses were carried out in the context of results for post-operative

adjuvant chemotherapy obtained by the Northern Japan Gastric Cancer Study Consortium

9 (13).

Methods

Patients

13 This study retrospectively analyzed 658 patients with primary GC who underwent R0

gastrectomy at one of 13 institutions located in Northern Japan (Hokkaido and Tohoku

area) between 2009 and 2013 (9). Sample and clinical information were collected by the

Northern Japan Gastric Cancer Study Consortium where the infection state of HP had

previously been pathologically confirmed (13). Patient characteristics of the subset for

the current study are shown in Supplementary Table 1. The multi-center study protocol

Koizumi et al -8-

1 was approved by the Institutional Review Board (IRB) of Iwate Medical University (H24-

132, HGH24-12, and HG2020-018), where all analysis was carried out. Ethical approval

for conducting this study was given by all IRB committees of all 12 participating

institutions listed in the Northern Japan Gastric Cancer Study Consortium at the Note

5 section.

Immunohistochemistry

A tissue microarray (TMA) including 658 gastric cancer specimens was made to perform 8

immunohistochemistry (IHC) (30). Of these, the HP infection status was available for 491

cases (13). In the present study, immunostaining reactions were performed using primary

antibodies against PD-L1 (22C3, Dako, Santa Clara, CA, USA, 1:50), CD4/CD8 (4B12)

and SP16, Biocare Medical, Concord, Pacheco, CA, USA, 1:100), and MMR proteins

including MLH1 (ES05, Agilent Technologies, Santa Clara, CA, USA, 1:80), MSH2

(FE11, Agilent Technologies, Santa Clara, CA, USA, 1:80), MSH6 (EP51, Agilent

Technologies, Santa Clara, CA, USA, 1:200), and PMS2 (EP49, Agilent Technologies,

Santa Clara, CA, USA, 1:50). Details of signal development protocols for each ICH are

described in the Supplementary Methods.

Scoring was performed by five individuals who had no knowledge of the clinical

background of the specimens. Three scientists [Y.K, S.A, S.S.N.] and two credentialed

1

Koizumi et al -9-

2 pathologists [R.S. and L.A.L.] judged the stained slides using an optical microscope. For PD-L1 scoring, cases having staining of >10% of all tumor tissues were defined as 3 4 positive. CD4/CD8 and total lymphocyte count (TLC) were recorded for three randomly selected fields at 40X magnification and the counts were averaged. Samples having a 5 count ≥1 and ≥18 for CD4 and CD8 cells, respectively, was defined positive. Samples 6 7 with TLC \geq 26 cells were defined as positive. Cases having complete loss of nuclear staining for at least one of the MMR proteins in tumor cells, but consistently preserved 8 9 nuclear staining in background, non-tumor cells, were considered as having deficient 10 MMR (dMMR). Staining for each MMR protein in < 30% of all tumor tissues was defined as negative. Samples in which nuclear staining was unaffected for all four MMR proteins 11 tested were judged as having proficient MMR (pMMR) (31) (Supplementary Figure 2). 12 13 14 MSI The MSI status could be determined for 100 cases, for which formalin fixed paraffin 15 16 embedded (FFPE) sections were available for extraction of tumor and normal genomic 17 DNA (FALCO biosystems Ltd, Waltham, MA, USA). Total DNA was extracted from FFPE tumor and paired normal tissue samples using a DNA extraction kit (Thermo Fisher 18

Koizumi et al -10-

1 Scientific, Waltham, MA, USA). MSI was evaluated with polymerase chain reaction

(PCR) using primers for relapse free survival (RFS) or five mononucleotide microsatellite

repeats (BAT-26, NR-21, BAT-25, MONO-27 and NR-24) according to a previously

described protocol (32). Tumors showing allelic shifts in at least one of five markers were

defined as MSI-positive (MSI⁺) and the remainder were defined as MSS normal, MSI-

negative (MSI⁻) (33, 34) (Supplementary Figure 1).

9 Categorical variable analysis was performed for parameters including PD-L1, CD4, CD8,

dMMR protein levels, MSI status, and clinicopathological characteristics to compare with

HP status using Fisher's exact test. OS and RFS were stratified by a combination of the

parameters and estimated by the Kaplan-Meier method. The log-rank test was used to

compare survival distributions, and the Cox proportional hazards model was used to

determine the hazards ratio (HR). For subgroup analysis, all interaction P values were

calculated with the likelihood ratio test. Survival time was defined from the date of

surgery. All statistical tests were two-tailed and a P value <0.05 was considered

statistically significant. Depending on the type of analysis, either JMP or GraphPad Prism

was used.

Koizumi et al -11-

Results

1

2

- Immunohistochemistry 3
- PD-L1 and CD4/CD8 IHC data were available for all 491 GC tumor samples (Table 1). 4
- There were 152 (31.0%) and 339 (69.0%) cases that were PD-L1⁺ and PD-L1⁻, 5
- respectively. The majority were CD4, (371 (75.6%) CD4⁻ cases vs. 120 (24.4%) CD4⁺ 6
- 7 cases), and for CD8, 252 (51.3%) cases and 239 (48.7%) cases were CD8⁺ and CD8⁻,
- respectively; The distribution of TLC status was similar (239 (48.7%) TLC⁺ cases vs. 252 8
- 9 (51.3%) TLC⁻ cases). MMR IHC data were available for 428 GC tumor samples and most
- 10 had pMMR (381 (89.0%) pMMR cases vs. 47 (11.0%) dMMR cases).
- 12 MSI

- Among 100 GC cases for which FFPE sections were available for extraction of DNA, 13
- 14 most were MSI⁻ (88 MSI⁻ cases (88%) vs. 12 MSI⁺ (12%) cases). Of the 12 MSI⁺ cases,
- 4 cases were HP⁺ and the remainder were HP⁻. Of the 88 MSI⁻ cases, 46 and 42 cases were 15
- HP⁺ and HP⁻, respectively. Furthermore, IHC results for MMR analyses were available 16
- 17 for 84 of the 100 samples. The concordance rate between IHC for MMR and MSI status
- was 83.3%. (Supplementary Table 2). 18

Survival status including OS and RFS were analyzed in terms of HP infection status (i.e., 3

HP⁺ or HP⁻) in conjunction with previously reported parameters (13, 35) and with 4

parameters from the current analysis (i.e., PD-L1, CD4, CD8, CD4/CD8, dMMR, and

6 TLC). For almost all subgroups, HP⁺ had longer OS and RFS times. An interaction

analysis by HP infection status revealed that S-1 (Full/Reduced) and PD-L1

(Positive/Negative) showed a potential interaction with P values of 0.049 and 0.016,

respectively (Figure 1).

Survival Status by HP

12 The survival status of the related subject cohort has been reported (13, 36, 37). Briefly,

outcomes were evaluated for 13.3 years (median 5.3 years) for the 491 patients. The

median traceable time for survival was 5.2 years. Among 162 censored cases within the

observation time, 109 and 53 cases were and were not cancer death, respectively. In the

present study, OS and RFS were analyzed in two groups stratified by HP infection status

in terms of PD-L1 level and S-1 treatment, which in the subgroup analysis exhibited an

interaction with HP infection status (Figure 1).

1 OS and RFS based on HP infection status were first assessed by stratifying PD-2 L1 level. The five-year OS rate in the PD-L1⁺/HP⁺ group and PD-L1⁺/HP⁻ was similar (69.9% (95%CI, 56.3-80.7%) vs. 72.9% (95%CI, 63.1-80.8%) (p=0.653; HR 0.879; 3 4 95%CI, 0.499-1.548; Figure 3A)), as was the five-year RFS rate (62.5% (95%CI, 48.9-5 74.4%) vs. 68.7% (95%CI, 58.8-77.2%) (p=0.598; HR 1.149; 95%CI, 0.683-1.935; Figure 3B). For the PD-L1⁻ subgroup, the five-year OS was higher for the PD-L1⁻/HP⁺ 6 group than the PD-L1⁻/HP⁻ group (80.6% (95%CI, 72.5-86.8%) vs. 67.9% (95%CI, 61.3-7 73.8%) (p=0.0011; HR 0.477; 95%CI, 0.303-0.751; Figure 3C), as was the five-year RFS 8 9 rate (75.6% (95%CI, 67.0-82.5%) vs. 62.6% (95%CI, 55.9-68.8%) (p=0.0011; HR 0.508; 10 95%CI, 0.335-0.771; Figure 3D). 11 Next, the subject patient population was narrowed down to consider those who 12 were eligible to receive post-operative S-1 adjuvant chemotherapy (i.e., exclusion of T3N0 tumors Stage II/III according to TNM classification ver. 7). Among these patients, 13 14 the five-year OS rate was similar between the PD-L1⁺/HP⁺ group (66.7% (95%CI, 51.4-79.2) and PD-L1⁺/HP⁻ group (67.9% (95%CI, 56.3-77.7; p=0.652; HR 0.871; 95%CI, 15 16 0.476-1.593; Figure 4A). The five-year RFS rate was also similar between the two groups 17 (PD-L1⁺/HP⁺ 57.5% (95%CI, 42.4-71.4) and PD-L1⁺/HP⁻ 63.9% (95%CI, 52.1-74.1; p=0.535; HR 1.191; 95%CI, 0.682-2.078; Figure 4B). The five-year OS rate for the PD-18

- $1~L1^{-}\!/HP^{+}$ group was 77.0% (95%CI, 67.5-84.4) and for the PD-L1 $^{-}\!/HP^{-}$ group was 62.7%
- 2 (95%CI, 54.8-69.9) (p=0.003; HR 0.497; 95%CI, 0.310-0.797; Figure 4C); whereas the
- 3 five-year RFS rate in PD-L1⁻/HP⁺ group was 70.7% (95%CI, 60.8-79.0) and for the PD-
- 4 L1⁻/HP⁻ group was 56.7% (95%CI, 48.8-64.1) (p=0.0022; HR 0.517; 95%CI, 0.336-
- 5 0.797; Figure 4D).
- Further analysis was performed to examine whether treatment effect (i.e.,
- 7 Surgery-only; and Surgery + S-1) could have affected the OS and RFS in the PD-L1
- 8 patients. The five-year OS rate in PD-L1⁻/Surgery-only/HP⁺ group was 71.4% (95%CI,
- 9 56.8-82.7%) and PD-L1⁻/Surgery-only/HP⁻ group was 68.4% (95%CI, 58.0-77.2%)
- 10 (p=0.367; HR 0.752; 95%CI, 0.404-1.40; Figure 5A); whereas the five-year RFS rate in
- 11 PD-L1⁻/Surgery-only/HP⁺ group was 67.0% (95%CI, 52.2-79.1%) and PD-L1⁻/Surgery-
- only/HP group was 65.1% (95%CI, 54.7-74.3%) (p=0.280; HR 0.721; 95%CI, 0.396-
- 13 1.313; Figure 5B). The five-year OS rate in the PD-L1⁻/Surgery + S-1/HP⁺ group was
- 14 82.3% (95%CI, 69.4-90.5%) and for the PD-L1⁻/Surgery + S-1/HP⁻ group was 55.3%
- 15 (95%CI, 43.5-66.6%) (p=0.0008; HR 0.304; 95%CI, 0.146-0.635; Figure 5C). The five-
- 16 year RFS rate in PD-L1⁻/Surgery + S-1/HP⁺ group was 74.3% (95%CI, 60.6-84.5%) and
- 17 PD-L1⁻/Surgery + S-1/HP⁻ group was 45.7% (95%CI, 34.3-57.5%) (p=0.0006; HR 0.350;
- 18 95%CI, 0.187-0.655; Figure 5D).

1 HP infection status appeared to be a strong discriminatory factor in the PD-L1 2 /Surgery + S-1 group. As such, the dose-related effect by S-1 was further analyzed for OS and RFS. The five-year OS rate in the PD-L1⁻/S-1 full dose/HP⁺ group was 77.3% (95%CI, 3 4 55.6-90.2%) and the PD-L1⁻/S-1 full dose/HP⁻ group was 65.0% (95%CI, 46.8-79.6%) 5 (p=0.164; HR 0.489; 95%CI, 0.176-1.361; Figure 6A). The five-year RSF rate in the PD-6 L1/S-1 full dose/HP⁺ group was 63.6% (95%CI, 42.3-80.7%) and PD-L1/S-1 in the full 7 dose/HP group was 58.6% (95%CI, 40.5-74.7%) (p=0.4171; HR 0.702; 95%CI, 0.297-1.660; Figure 6B). The five-year OS rate in PD-L1⁻/S-1 reduced/HP⁺ group was 86.2% 8 9 (95%CI, 68.5-94.7%) and PD-L1⁻/S-1 reduced/HP⁻ group was 46.4% (95%CI, 31.2-10 62.3%) (p=0.0014; HR 0.205; 95%CI, 0.07-0.602; Figure 6C); whereas the five-year RFS 11 rate in PD-L1⁻/S-1 reduced/HP⁺ group was 82.8% (95%CI, 64.7-92.6) and PD-L1⁻/S-1 reduced/HP⁻ group was 34.2% (95%CI, 21.0-50.4%) (p=0.001; HR 0.190; 95%CI, 0.072-12 13 0.498; Figure 6D). 14 15 Multivariate Analysis 16 To examine which parameters may be independent factors for OS or RSF, a Cox 17 proportional hazards regression model to examine interaction among the following parameters: age, sex, pathological stage (pStage) (TNM7), S-1 Dose, histologic type, 18

Koizumi et al -16-

1 CD4, CD8, TLC, MSI, MMR, and HP*PD-L1 was carried out. There were 54 events for

RSF and OS (Figure 3). To avoid overfitting, five parameters were thus selected for each

analysis. Overall, the statistical model identified as independent factors pStage (TNM7),

and HP*PD-L1 for advanced GC patients with >2-fold hazard ratio in the present cohort

5 (Table2).

Discussion

The improved survival seen for advanced GC patients who are HP⁺ compared to those 8

who are HP suggests that systemic effects that are chronically induced by HP infection

may play a significant role in GC treatment efficacy (13, 37). Importantly, many countries

have reported similar trends, suggesting that the HP infection could have more dominant

effects than a variety of treatments that are delivered in different countries and regions

(10, 12, 38). For instance, the standard therapy for advanced GC varies between East Asia,

Europe and North America due to heterogeneities in tumors, race, medical environment

and surgical procedures (6, 39-41). However, whether HP infection actually induces a

systematic effect that is directly related to the OS is unclear. Moreover, HP infection is

thought to be related to gastric duodenal ulcer, idiopathic thrombocytopenic purpura,

MALT lymphoma and hyperplastic polyps although most of these diseases are unlikely 18

Koizumi et al -17-

1 to directly cause death (42-45). These diseases occur only in a small percentage of people 2 infected with HP, suggesting that HP infections can frequently persist in the host without causing disease (46). Clarification of the systematic mechanisms induced by HP infection 3 4 is important since HP may have effects other than tumor induction in the majority of infected people, even though a small percentage of healthy individuals do develop GC 5 simply due to HP infection (47). 6 Standardized radical gastrectomy for Stage II/III (TNM7) GC followed by S-1 adjuvant chemotherapy is a well-established treatment protocol in Japan (7). However 8 9 our consortium included "surgery only" patients who underwent surgery before 2006. 10 Therefore, although retrospective, our present data allow an important comparison to 11 assess the effect of HP in patients who received S-1 adjuvant chemotherapy as the community standard in Japan. By profiling immune-response molecules in advanced GC 12 patients, we demonstrated that prognosis of HP⁺ was significantly better than HP⁻ patients 13 14 in the PD-L1⁻ population. This result was further pronounced by stratification of the patients in order with R0 operation, Stage II/III, S-1 adjuvant chemotherapy, and dose 16 reduced S-1 adjuvant chemotherapy. In terms of OS and RFS, the status of other immunerelated molecules, including CD4, CD8, TLC, and MMR proteins as well as the status of

MSI did not show significant association with PD-L1 levels or HP infection status. In the

background microenvironment, HP infection induces PD-L1 expression and T-cell activation (48). Upregulation of PD-L1 on gastric epithelial cells may serve as one negative feedback mechanism for tissue protection during T-cell inflammatory events, whereby PD-L1 delivers an inhibitory signal to T-cells (27, 49). It has been reported that the level of PD-L1 expression on gastric epithelial cells is intrinsically modulated by chronic HP infection (49, 50). An upregulation of PD-L1 expression in gastric epithelium increases the chance to trigger malignant transformation (27). In advanced GC, S-1 administration of a standard dose and regimen is associated with a favorable prognosis (51, 52), whereas our present data suggest that HP⁺ patients who do not have sustained PD-L1 levels on cancer cells have a potential survival benefit despite reduced adjuvant chemotherapy. In general, HP infection occurs in early age, whereas GC develops 40-50 years after exposure of HP infection (53, 54). Further investigation is warranted to clarify the way in which the degree of HP infection and subsequent host response can be individually differentiated. All 491 cases were analyzed by the Cox proportional hazards model, which identified pStage (TMN7) and HP*PD-L1 as independent prognostic factors with a >2fold hazards ratio. While pStage (TMN7) and age are generally associated with prognosis (7, 55), HP status and systemic immune conditions have not been investigated. Based on

Koizumi et al -19-

1 our current data, the identification of HP*PD-L1 as one of the prognostic factors suggests

that HP infection status can provide treatment stratification for locally advanced GC

patients who undergo adjuvant chemotherapy after gastrectomy.

The present study has the following limitations: (a) it was a retrospective study;

(b) S-1 treatment indication was not randomized; (c) information was occasionally

missing due to sample preserved conditions; (d) histological heterogeneity was not taken

into account due to limited sample area; and (e) HP infection status was only assessed by

histological examination. Nonetheless, our rigorous approach still suggests that PD-L1

and HP infection status have a substantial impact on the stratification of advanced GC

patients.

17

Conclusion

For advanced GC patients who undergo postoperative chemotherapy, HP-dependent 13

modulation of PD-L1-influenced host immune system function could contribute to

prolonged survival time in the absence of functioning immune escape mechanisms.

Table 1: Immunohistochemical characteristics of patients with HP⁺ and HP⁻ advanced GC.

1

2

		Н	Р	P value
		+	_	
PD-L1	+	54	98	1.0000
	-	121	218	
CD4 T-cell	+	37	83	0.2285
	-	138	233	
CD8 T-cell	+	86	166	0.5097
	_	89	150	
TLC	+	85	154	1.0000
	_	90	162	
MMR	+	16	31	0.8724
	_	138	243	
MSI	+	4	8	0.3567
	_	46	42	

⁴ Fisher's exact test was used to compare clinicopathological variables. A p-value <0.05 was

⁵ considered statistically significant. Total lymphocytes count, TLC; microsatellite instability, MSI.

Koizumi et al -38-

Table2: Effect of parameters to OS by Cox proportional hazards regression model

1

2

	Hazard ratio	Wald chi-square P value
HP*PD-L1	2.01	0.0019
Age	0.636	0.0101
Sex	0.735	0.0889
S-1 dose	0.721	0.2997
pStage (TNM7)	2.201	0.0009

- 4 HP*PD-L1 was divided into "HP+/ PD-L1-" as 1 otherwise 0. Also, pStage (TNM7) was divided into IB
- 5 group as 1 and otherwise 0. Wald chi-square p-value < 0.05 was considered statistically significant.
