ABSTRACT

Recent studies have indicated that extracellular vesicles (EV) may play a role in the pathogenesis of Acute Respiratory Distress Syndrome (ARDS). EV have been identified as potential biomarkers of disease severity and prognosis in other pulmonary diseases. We sought to characterize the EV phenotype within ARDS patient broncho-alveolar lavage fluid (BAL), and to determine whether BAL EV could be utilized as a potential biomarker in ARDS. EV from the BAL of sepsis patients with ARDS, sepsis patients without ARDS, and post-operative control patients were characterized with regards to size, number and cell of origin. ARDS patients had significantly higher numbers of $CD14^+/CD81^+$ monocyte-derived BAL EV than sepsis patients without ARDS (p=0.022). $CD14^+/CD81^+$ BAL EV numbers were significantly higher in those ARDS patients who died during the 30 days following ICU admission (p=0.027). Also, across all sepsis patients there was an association between $CD66b^+/CD63^+$ neutrophil-derived BAL EV and increased BAL IL-8 concentration, increased alveolar neutrophil apoptosis and decreased alveolar macrophage efferocytosis. Thus, $CD14^+/CD81^+$ BAL EV are a potential biomarker for disease severity and mortality in ARDS. These findings provide the impetus to further elucidate the contribution of these EV to ARDS pathogenesis.

Key Words: Acute Respiratory Distress Syndrome, Sepsis, Extracellular Vesicles, Broncho-Alveolar Lavage, Monocyte.

INTRODUCTION

Acute Respiratory Distress Syndrome (ARDS) is a hyper-inflammatory pulmonary disorder, which most commonly develops following sepsis. Neutrophilic inflammation and alveolar-capillary barrier damage lead to alveolar edema and refractory hypoxia, requiring prolonged mechanical ventilation (1). Mortality remains high at 35-45% (2). Survivors have long-term morbidity and increased risk of developing lung fibrosis. There is an urgent need to identify novel therapeutic targets for ARDS, especially due to the evolving SARS-CoV-2 pandemic in which ARDS is the main cause of mortality (3).

Extracellular vesicles (EV) are membrane-bound anuclear structures which constitute an inter-cellular communication mechanism (4). EV allow targeted transfer of diverse biologic cargo (including mitochondria, RNA, cytokines) between different cell types (5). Uptake of EV can alter gene expression within host cells (6). The tetraspanins CD9, CD63 and CD81 are transmembrane proteins commonly expressed on EV, and can be used to isolate EV in acellular biofluids (7). There are two main subtypes of EV: exosomes and microvesicles. Exosomes are 30-150nm in diameter and form by fusion of multi-vesicular bodies with the plasma membrane, whereas microvesicles are 100-1000nm in diameter and form by outward blebbing of the plasma membrane (4). With an overlap in size and some common markers (e.g. tetraspanins) differentiating exosomes and microvesicles is challenging, however Endosomal Sorting Complex Required for Transport (ESCRT) proteins such as syntenin are candidate internal cargo marker specific to exosomes (8).

Recent evidence indicates that EV play an important role in ARDS pathogenesis by promoting persistent inflammation. Pathogenic EV are released when human *ex-vivo*

perfused lungs are injured with *E. coli*; isolation of these EV and administration to uninjured human lungs can also induce inflammatory lung injury (9). Murine models of lipopolysaccharide lung injury have shown that EV transfer of microRNA cargo (e.g. miR-466) to alveolar macrophages can increase inflammatory cytokine release (10). Recent studies have indicated that CD14[+] BAL EV may be a potential biomarker for disease activity in COPD (11).

We have previously shown that alveolar macrophages isolated from patients with sepsis-related ARDS have impaired efferocytosis (ability to clear apoptotic cells) compared to control ventilated sepsis patients without ARDS (12). Alveolar macrophage efferocytosis negatively correlated with alveolar neutrophil apoptosis, and broncho-alveolar lavage (BAL) cytokines IL-8 and IL-1α. Impaired efferocytosis was associated with increased 30-day mortality and duration of mechanical ventilation, indicating that this alveolar macrophage functional defect contributes to ARDS pathogenesis (12). Treatment of healthy alveolar macrophages with BAL from ARDS patients also impairs efferocytosis and downregulates Rac1 expression (which causes cytoskeletal rearrangement allowing apoptotic cell engulfment), reproducing the same functional defect observed in ARDS (13). However, the causative immunomodulatory factors within ARDS patient BAL are yet to be identified. Identification of differentially expressed EV populations within ARDS BAL may guide further investigation into the mechanism of this alveolar macrophage functional defect

In this study, the objective was characterize the EV phenotype of ARDS patient BAL and to compare this EV population to that in control sepsis and post-operative patients at-risk of developing ARDS. We also aimed to determine whether BAL EV could be utilized as a potential biomarker in ARDS.

MATERIALS AND METHODS

Ethical Approval

As previously described (12), ethical approval was obtained to recruit ventilated sepsis patients with and without ARDS (REC 16/WA/0169). Ethical approval was also obtained to recruit patients undergoing transthoracic esophagectomy for esophageal carcinoma (REC 12/WM/0092) as previously described in the VINDALOO trial (14, 15). For patients who lacked capacity, permission to enroll was sought from a personal legal representative in accordance with the UK Mental Capacity Act (2005). For patients with capacity, written informed consent was obtained from the patient.

Patient recruitment and broncho-alveolar lavage

Invasively ventilated adult sepsis patients with and without ARDS were recruited from the intensive care unit of the Queen Elizabeth Hospital Birmingham, U.K. from December 2016 – February 2019 and BAL was collected as previously described, within 48 hours of initiation of mechanical ventilation (12). Patient demographic and physiological details can also be found in this prior publication. As part of the VINDALOO trial (15), patients underwent post-operative bronchoscopy and BAL following oesophagectomy. Following unblinding of the study, those patients who received placebo and who had not developed ARDS during their post-operative course were identified; BAL samples from 8 of these at-risk post-operative patients were analyzed in this study. For all patients, BAL fluid was rendered acellular by

centrifuging at 500g for 5 minutes then stored at -80°C prior to use in this study. Differential cell count was performed on cells isolated from BAL.

BAL Extracellular Vesicle characterization

A single-particle interferometric reflectance image sensing platform was used (Exoview R100 reader, NanoView Biosciences, USA) to detect and characterize EV size, number and surface marker expression within BAL samples [16]. The Exoview platform allows quantification and phenotyping of EV as small as 50nm in diameter [7]. EV numbers in BAL were measured using ExoView™ Tetraspanin kits (NanoView Bioscience, USA) according to manufacturer's instructions. Human BAL samples were diluted with incubation solution at a 1:20 dilution. 35 µl of diluted BAL was loaded on the ExoView Tetraspanin chips and incubated for 16 hours in a sealed, humidified 24-well plate at room temperature to allow EV binding. Each chip contained spots printed with mouse anti-human antibodies against the tetraspanins CD63 (clone H5C6), CD81 (clone JS81) and CD9 (clone H19a) which enabled EV capture. Chips also contained mouse IgG1κ matching isotype antibody, used as a control for non-specific EV binding. Chips were washed three times with incubation solution; after each wash the plate was shaken at 500rpm (LSE digital microplate shaker, Corning, USA). Chips were stained with a fluorescent antibody cocktail for 1 hour at room temperature in the dark to characterize EV surface markers. Fluorophore-conjugated mouse anti-human antibodies included: CD14-APC (1:100 dilution, clone 61D3, Invitrogen), CD206-Phycoerythrin (1:100 dilution, clone 19.2, Invitrogen), EpCam-AlexaFluor488 (1:400 dilution, clone 94C, BioLegend), CD66b-AlexaFluor647 (1:200 dilution, clone G10F5, BD Biosciences), CD31-Phycoerythrin (1:100 dilution, clone WM59, Invitrogen), and CD41-AlexaFluor488

(1:400 dilution, clone HIP8, BioLegend). Chips were washed thrice as described above, with a final wash in distilled water. Chips were then imaged using the ExoView R100 reader and nScan2 v2.76 software. Data were analyzed using NanoViewer v2.82, using mouse IgG capture spots as negative control (indicative of non-specific binding) for fluorescent gating, and EV sizing thresholds set at 50-200nm diameter. EV cell origin data were correlated with previously recorded clinical outcomes and immune cell functional parameters (12) to identify potential biomarkers. Data from each tetraspanin capture spot (CD63, CD81 and CD9) was calculated separately by subtracting negative control values from IgG spots.

Statistical Analysis

Data were analyzed using Prism 8 software (GraphPad, USA). Parametric data shown as mean and standard deviation. Non-parametric data shown as median and interquartile range. Differences between continuously distributed data assessed using t-tests for parametric data, or Mann-Whitney tests for non-parametric data. Differences between three or more unpaired non-parametric data sets assessed using Kruskal-Wallis Analysis of Variance (ANOVA) followed by Dunn's multiple comparison tests. Two-tailed p-values of ≤0.05 were considered significant.

RESULTS

The demographic and clinical characteristics of patients from each of the three cohorts analyzed are shown in **Table 1**. BAL samples were analyzed from 17 sepsis patients with ARDS, 14 sepsis patients without ARDS and 8 post-operative patients.

BAL EV were characterized with regards to size, number and surface marker expression to indicate cellular origin. The size distribution of BAL EV did not differ among the three patient groups (**Figure 1A**). Representative fluorescence images from the Exoview platform demonstrating EV surface marker expression and lack of non-specific binding are shown in **Figure 1B-E**.

Characterization studies showed that a greater number of CD14$^+$ EV were present in the BAL of ARDS patients compared to sepsis patients without ARDS, detected by CD81$^+$ tetraspanin capture (**Figure 2A,** medians 1.23 x10^8/ml vs 6.26 x10^7/ml, p=0.026). CD66b$^+$ BAL EV were elevated in ARDS patients compared to post-operative control patients, detected by CD63$^+$ tetraspanin capture (**Figure 2B**, medians 4.65 x10^7/ml vs 5.22 x10^6/ml, p=0.029). CD31$^+$ BAL EV were elevated in post-operative control patients compared to sepsis patients with and without ARDS, detected by CD9$^+$ tetraspanin capture (**Figure 2C**, p<0.018). CD41$^+$ BAL EV were decreased in the post-operative control group compared to sepsis patients with and without ARDS, detected by CD63$^+$ tetraspanin capture (**Figure 2D**, p<0.014). There were no differences in the numbers of CD206$^+$ and EpCam$^+$ BAL EV between sepsis patients with and without ARDS (**Figure 2E-F**).

In sepsis patients with ARDS, those who died within 30 days of ICU admission had a greater number of CD14$^+$/CD81$^+$ BAL EV than survivors (**Figure 3A,** medians 3.43 x10^8 /ml vs 9.54 x10^7 /ml, p=0.027), however there is overlap between groups. Across all sepsis patients with and without ARDS, CD66b$^+$/CD63$^+$ BAL EV correlated directly with BAL interleukin (IL)-8 concentrations, (**Figure 3B**, r=0.751, p<0.0001). Across all sepsis patients with and without ARDS, CD66b$^+$/CD63$^+$ BAL EV correlated inversely with alveolar macrophage efferocytosis index (**Figure 3C**, r=-0.612, p=0.0025).

DISCUSSION

In this study, sepsis patients with ARDS had significantly higher numbers of $CD14^+/CD81^+$ BAL EV than sepsis patients without ARDS. $CD14^+/CD81^+$ BAL EV numbers were significantly higher in those ARDS patients who died during the 30 days following ICU admission. $CD206^+$ EV numbers were unchanged in ARDS patients (CD206 being an alveolar macrophage marker), indicating that the increased $CD14^+$ EV observed in ARDS patients were derived from infiltrating monocytes as opposed to resident alveolar macrophages. CD14 has previously been used as a marker of monocyte-derived EV (17). The relationship between $CD14^+/CD81^+$ BAL EV and mortality in ARDS patients is in keeping with previous studies showing that the degree of monocyte influx in ARDS can correlate with the severity of respiratory failure (18). Previous studies have shown that monocyte-derived plasma EV containing gasdermin D and activated caspase-1 are more abundant in patients with sepsis-related ARDS compared to healthy controls; uptake of these EV can induce death in human pulmonary vascular endothelial cells (19). This data supports our hypothesis that $CD14^+$ EV may contribute to ARDS pathogenesis, and might be utilized as a biomarker of disease severity.

We also observed associations between $CD66b^+/CD63^+$ neutrophil-derived BAL EV in sepsis patients and increased BAL IL-8 concentration and decreased alveolar macrophage efferocytosis. These data indicate that $CD66b^+/CD63^+$ BAL EV may be a marker of inflammation in ARDS. Neutrophil-derived EV have been shown to have an anti-inflammatory, tolerogenic impact following uptake by macrophages and T lymphocytes (20-22). Previous studies have also reported that neutrophil-derived EV can transfer microRNA-

223 to alveolar epithelial cells, which reduces protein permeability and cytokine release via repression of poly[adenosine diphosphate−ribose] polymerase−1 (PARP-1) (23). Therefore, the increased number of CD66b$^+$ EV in patients with a more inflammatory alveolar microenvironment may be a compensatory response to suppress inflammation and reduce alveolar epithelial injury.

Our findings of decreased CD31$^+$/CD9$^+$ EV and increased CD41$^+$/CD63$^+$ EV in sepsis patients with and without ARDS compared to post-operative control patients may be indicative of pathological processes common to all sepsis patients. Previous studies have shown that platelet-derived EV can induce endothelial cell apoptosis in sepsis patients (24). However, no difference in CD31$^+$ and CD41$^+$ EVs was observed between sepsis patients with and without ARDS, therefore conclusions cannot be drawn regarding the relevance of these EV in ARDS pathogenesis.

EV transfer of microRNA cargo to murine macrophages can alter metabolic profile and function (25); EV transfer of long non-coding RNA can promote glycolysis (26). An association between impaired alveolar macrophage efferocytosis and dependence on glycolysis has been observed in COPD patients (27). Further studies are required to determine if similar pathological processes occurs in ARDS, specifically whether CD14$^+$ EV transfer of microRNA or protein cargo induces alveolar macrophage dysfunction (12), thereby promoting persistent inflammation. Understanding the role of EV in ARDS pathogenesis will allow identification of potential EV / microRNA biomarkers and novel therapeutic targets for ARDS.

A limitation of our study is that while we identified EV from the major cell types present in the alveolar space, not all cellular origins were included in our analysis (e.g.

dendritic cells, lymphocytes). Although tetraspanin capture of EVs provides greater EV specificity compared to other isolation methods, it also limits phenotyping, and therefore only provides an indication of the relevance of CD14$^+$ EV. The finding that CD14 most commonly co-localises with tetraspanin CD81, and CD66b with tetraspanin CD63, may indicate different EV biogenesis pathways in monocytes and neutrophils respectively (28). Future studies are required to specifically capture CD14$^+$ and CD66b$^+$ EV, then to probe external markers for extensive phenotyping, and internal markers (e.g. syntenin) to determine EV biogenesis pathways .

In conclusion, we report that CD14$^+$/CD81$^+$ BAL EV are enriched in patients with sepsis–related ARDS compared to controls, and that an elevated CD14$^+$/CD81$^+$ BAL EV count is associated with increased mortality in ARDS patients, although the sample size is modest. Thus, CD14$^+$ BAL EV are a potential biomarker for disease severity and mortality in ARDS. Our findings provide the impetus to further elucidate the role these EV play in ARDS pathogenesis.

Ethical Approval
Ethical approval was given by the Wales Research Ethics Committee 1 (reference number 16/WA/0169) to recruit ventilated sepsis patients with and without ARDS. Ethical approval was also given by the South Birmingham (England) Research Ethics Committee (reference number 12/WM/0092) to recruit patients undergoing transthoracic esophagectomy for esophageal carcinoma as previously described in the VINDALOO trial. For patients who lacked capacity, permission to enroll was sought from a personal legal representative in accordance with the UK Mental Capacity Act (2005). For patients with capacity, written informed consent was obtained from the patient.

Grants

This work was funded by Medical Research Council grants MR/N021185/1 (RYM) and MR/L002736/1 (DT/AS), and by National Heart, Lung and Blood Institute grants HL134828 (MAM) and HL140026 (MAM). The ExoView platform was funded by an EPSRC Capital award awarded to Dr. Sophie Cox, University of Birmingham.

Specificities of exosome versus small ectosome secretion revealed by live intracellular tracking of CD63 and CD9. *Nature communications* 12: 4389, 2021.

Table 1: Patient demographic and clinical characteristics

	Sepsis patients with ARDS (n=17)	Sepsis patients without ARDS (n=14)	Post-operative patients (n=8)
Demographics			
Age in years:	59.2 (13.9)	55.1 (16.3)	65.8 (7.9)
Male Gender: n (%)	15 (71%)	11 (65%)	4 (50%)
Ethnicity: Caucasian - n (%)	21 (100%)	17 (100%)	7 (88%)
Smoking status: n (%)			
- **Current**	7 (33%)	5 (29%)	0 (0%)
- **Ex-smoker**	9 (43%)	6 (35%)	6 (75%)
- **Never smoker**	2 (10%)	1 (6%)	2 (25%)
- **Unknown**	3 (14%)	5 (29%)	0 (0%)
ICU LoS in days: median (IQR)	23.0 (12.8 − 33.8)	12.0 (7.5 − 19.0)	4.5 (2.5 − 7.8)
Hospital LoS in days: median (IQR)	33.0 (15.3 − 52.5)	24.0 (13.0 − 39.5)	12 (8.3 − 15.8)
Ventilator Free Days to day 28:	6.9 (9.2)	15.9 (8.3)	26.3 (1.8)
Inpatient Mortality: n (%)	7 (33.3%)	3 (17.6%)	0 (0%)
BAL leukocyte count x10^6: median (IQR)	15.8 (7.4 − 31.3)	6.4 (3.8 − 27.0)	7.8 (2.1 − 10.5)
% Neutrophils in BAL:	69.9 (21.5)	49.0 (30.6)	9.5 (10.1)

IQR = Interquartile range. LoS = Length of stay. ICU = Intensive care unit. Data are presented as mean (standard deviation) unless otherwise indicated.
