Background: Non-invasive oxygen saturation (SpO₂) measurement is a central vital sign that supports the management of COVID-19 patients. However, reports on SpO₂ characteristics (patterns and dynamics) are scarce and none, to our knowledge, has analysed high resolution continuous SpO₂ in COVID-19. **Methods:** SpO₂ signal sampled at 1Hz and clinical data were collected from COVID-19 departments at the Rambam Health Care Campus (Haifa, Israel) between May 1st, 2020 and February 1st, 2021. Data from a total of 367 COVID-19 patients, totalling 27K hours of continuous SpO₂ recording, could be retrieved, including 205 non-critical and 162 critical cases. Desaturations based on different SpO₂ threshold definitions and oximetry derived digital biomarkers (OBMs) were extracted and compared across severity and support levels. **Findings:** An absolute SpO₂ threshold at 93% was the most efficient in discriminating between critical and non-critical patients without support or under oxygen support. Under no support, the non-critical group depicted a fold change (FC) of 1-8 times more frequent desaturations compared to the critical group. However, the hypoxic burden was 1-6 times more important in critical versus non-critical patients. Other OBMs depicted significant differences, notably the percentage of time below 93% SpO₂ (CT93) was the most discriminating OBM. Mechanical ventilation depicted a strong effect on SpO₂ by significantly reducing the frequency (1-85 FC) and depth (1-21 FC) of desaturations. OBMs related to periodicity and hypoxic burden were markedly affected up to several hours before the initiation of the mechanical ventilation. **Interpretation:** This is the first report investigating continuous SpO₂ measurements in hospitalized patients affected with COVID-19. SpO₂ characteristics differ between critical and non-critical patients and are impacted by the level of support. OBMs from high resolution SpO₂ signal may enable to anticipate clinically relevant events, monitoring of treatment response and may be indicative of future deterioration. **Funding:** The Milner Foundation, The Placide Nicod foundation and the Technion Machine Learning and Intelligent Systems center (MLIS).

COVID-19 | Pulse oximetry | Continuous monitoring | Intensive care

Introduction

The ongoing coronavirus disease 2019 (COVID-19) pandemic has spread all over the world and caused, as of early August 2021, over 4-3 million deaths. Approximately 15-20% of confirmed cases develop severe disease, while the fatality rate is 2-5%¹⁻³ depending on the country and the monitored period.

NOTE: This preprint reports new research that has not been certified by peer review and should not be used to guide clinical practice.

In hospitalized patients with acute respiratory infections, such as patients with COVID-19, continuous SpO₂ monitoring has become central and is used to detect desaturation events required for patient triage, risk stratification and escalation of treatment, and to allow the clinicians to track the response to therapeutic interventions such as oxygen enrichment or ventilation^{4,5}. Specifically in COVID-19 patients, SpO₂ is often used in the ROX score (ratio of SpO₂/FIO₂ to respiratory rate) or in the SpO₂/FiO₂ ratio to predict the future need for oxygen support or mechanical ventilatory support and the success of a therapy⁶⁻⁸. Nevertheless, these studies rely mostly on admission data or discrete measurements during hospitalization. To our knowledge, no study investigated continuous high resolution SpO₂ characteristics (patterns and dynamics) in COVID-19 patients.

Methods

The present work aims to describe high resolution SpO₂ signal characteristics and potential usage along the treatment course for non-critical, critical with or without oxygen support and critical mechanically ventilated patients. The specific objectives of this work are: (1) Determining global SpO₂ signal characteristics correlated with disease severity and/or the level of respiratory support; (2) Investigating the optimal definition of a relative or absolute threshold for defining clinically relevant desaturations; (3) Defining characteristics of the SpO₂ signal including desaturation parameters and oximetry derived digital biomarkers (OBMs) allowing for the differentiation between critical and non-critical groups or those affected by the level of support; (4) highlighting the potential of OBMs extracted from high resolution SpO₂ signal for the detection of early signs of deterioration leading to the indication of mechanical ventilation and for tracking patient's response to medical treatment.

Study design and participants. This single center retrospective observational cohort study used electronic medical records (EMR) and continuous physiological monitoring data from Rambam Health Care Campus (HCC), a 1000-bed tertiary academic hospital in Northern Israel. During the pandemic the Rambam HCC opened five dedicated COVID-19 departments. The hospital EMR database was queried for hospitalized adult (age 18 and above) cases admitted for COVID-19, from May 1st 2020 until February 1st 2021 with

Research in context

Evidence before this study

COVID-19 is a viral infection due to the SARS-COV2 virus that can lead to acute respiratory distress syndrome (ARDS). Non-invasive oxygen saturation (SpO₂) measurement is a central vital sign that supports the management of COVID-19 patients. In recent research, SpO₂ measures performed at admission or discrete measures of SpO₂ during the first few days of hospitalization have been described as good predictors of mortality or for the need for invasive ventilation. In addition, self-monitoring at home of mild cases of COVID-19 using a pulse oximeter was recommended by physicians in a recent research study to decide if a patient should be admitted to the hospital. Despite the apparent importance of SpO₂ measurements in COVID-19 management, reports on SpO₂ characteristics are scarce and no research, to our knowledge, has analyzed high resolution continuous SpO₂.

Added value of this study

Our work is the first systematic analysis of the SpO₂ patterns and dynamics across the spectrum of COVID-19 disease severity and respiratory support. Specifically, our study investigated two definitions and multiple thresholds to define clinically relevant desaturation events. An absolute SpO₂ desaturation threshold at 93% was the most efficient in discriminating between critical and non-critical patients without respiratory support or under oxygen support. Using the 93% SpO₂ threshold, non-critical patients had more frequent shallow desaturations, while critical patients had deeper and longer but less numerous desaturations. Beyond the detection of desaturations, the percentage of time below 93% SpO₂ was the most discriminating feature between critical and non-critical patients with no support and with oxygen support. Oxygen support markedly reduced the differences between non-critical and critical patients by decreasing the ability of oximetry biomarkers (OBMs) to discriminate between the two groups despite the fact that SpO₂ signal was still driven by the underlying physiology. On the other hand, mechanical ventilation strongly impacted SpO₂ signal by significantly reducing the frequency of desaturations, the depth and most OBMs. In addition, patients mechanically ventilated showed a higher SpO₂ saturation level overall with a risk of over oxygenation. Beyond hypoxic burden or desaturations, which shows high variation up to an hour before mechanical ventilation initiation, some OBMs related to the power spectral density depict strong perturbations up to several hours before. This suggests that OBMs derived from high resolution SpO₂ signal may be used as early signs of deterioration.

Implications of all the available evidence

SpO₂ is extensively used in clinical practice to monitor COVID-19 patients. Our data suggests that a desaturation threshold of 93% is suited for monitoring hospitalized COVID-19 patients. Thus, a more stringent threshold is preferred to the WHO guidelines that define an operational threshold at 90% to identify severe patients. We found that the percentage of time under 93% oxygen is the best single OBM reflecting the future need for respiratory support and our findings motivates that attention should be given to this feature by the clinical staff. In addition, we have seen that other OBMs, used in the field of sleep medicine, could be informative for assessing the patient's response to respiratory support and to provide early signs of deterioration that will lead to the initiation of mechanical ventilation. Overall, high resolution SpO₂ data contains rich information concerning the patients' health status that are currently under exploited. This study provides the basis motivating the usage of continuous SpO₂ signal for the development of decision support tools to improve hospitalized COVID-19 patients care and potentially other ARDS.

at least one hour of continuous SpO₂ recording. During this period, 1810 confirmed COVID-19 cases were admitted to the Rambam HCC (Figure S1). Most cases were mild or moderate and were not necessarily connected to a bedside monitor for continuous surveillance. Five hundred and nineteen patients above 18 years of age were monitored and 367 had more than an hour of SpO₂ continuous measurement. Consequently, we collected continuous physiological signal from 162 critical and 205 non-critical COVID-19 patients. Identified waveform data from all COVID-19 units (ward and intensive care unit, ICU) were included. Data were extracted from MINDRAY monitors (Shenzhen, China). Using the MINDRAY software CMSViewer, the available SpO₂ data per patient were exported with a resolution of 1Hz. Overall 27K hours of continuous SpO₂ signal was collected, including 15K hours on patients breathing room air, 4K hours of mechanically ventilated patients, and 8K hours for patients

under oxygen support. Preprocessing of the raw SpO₂ signal was performed using a block filter as in Levy et al.⁹ and a smoothing moving median filter with a window of 9s. EMR data including demographics information for age, sex, weight, body mass index (BMI), length of hospitalization, disease severity, and mortality rates were collected. In addition, monitor information such as the end-tidal CO₂ (ETCO₂) channel for mechanical ventilation, parameters and timestamps, oxygen support and respiratory information including oxygen flow rate, and respiratory rate were collected. Ethical approval for this research was provided by the local institutional review board under IRB #0141-20.

COVID-19 definition and severity groups. As in Benaim et al.¹⁰, and following existing guidelines¹¹⁻¹³, COVID-19 positive patients were defined as follow: at least one positive reverse transcription polymerase chain reaction (RT-PCR) test for SARS-CoV-2 in nasopharyngeal swab. Crit-

ically ill patients were defined for their entire hospitalization as those who either received mechanical ventilation support (invasive or non-invasive), were hospitalized in an ICU, or were administered vasopressors (Noradrenaline or Vasopressin) or inotropes (Dopamine, Dobutamine, Milrinone, or Adrenaline).

Oxygen and mechanical ventilatory support. Oxygen support intervals were defined based on the first and the last continuous value of oxygen flow rate extracted from the EMR for an individual patient (Figure S2). Mechanical ventilation intervals were detected using the End-tidal CO₂ (EtCO₂) channel from the monitors. The EtCO₂, which measures the partial pressure of CO₂ at end expiration, is recorded only in mechanically ventilated patients. The SpO₂ data were split according to an overlap with these predefined intervals. Oxygen delivery and ventilation modes were recorded, including continuous positive airway pressure (CPAP), bi-level positive airway pressure (BIPAP), mask, nasal prongs, T-tube and a tracheostomy mask. Several equipment types were used, notably ventilators such as Hamilton (Hamilton Medical, Bonaduz, Switzerland), ServoAIR, Servo I (Getinge, Gothenburg, Sweden), EVITA (Dräger, Lübeck, Germany), VELA (VYAIRE MEDICAL INC., Chicago, Illinois, United States) and high flow oxygen delivery devices such as Airvo2 (Fisher and Paykel, Auckland, New Zealand) and Vapotherm (Vapotherm Inc., Exeter, New Hampshire, United States).

Events definition.

Desaturation events. Two categories of desaturations can be defined: (1) "relative" desaturations corresponding to a decrease of x% (here taken as 3% or 5%) of the SpO₂ signal, before returning to 1% below the initial saturation level. The relative threshold desaturation detector is based on the Oxygen Desaturation Index (ODI) which is traditionally used in sleep medicine. The ODI algorithm from Jung et al.¹⁴ was used with its implementation and validation by Behar et al.¹⁵; (2) "hard" desaturations defined as SpO₂ level falling below a given threshold of x% SpO₂ (here taken as 93%, 90% or 88%). When the SpO₂ signal falls below this value, a desaturation is detected. Figure 1 presents examples of desaturations detected using the hard threshold and relative threshold. The event has to be of a minimum length of 120 seconds. This is to be considered a desaturation event to avoid a false positive reading caused by the patient's movements or noise. For each detected desaturation, several desaturation parameters were extracted. Specifically area, length, depth, time between the beginning and the minimum point (defined as desat. time), the time between the minimum and the end (defined as resat. time) and the duration between two consecutive desaturations (interval time).

Transition to mechanical ventilation event. For each patient in the critical group, the time of initiation of mechanical ventilation was extracted on the EtCO₂ channel using a sliding window procedure. Briefly, two consecutive windows of five seconds long were created. When sliding the two consecutive

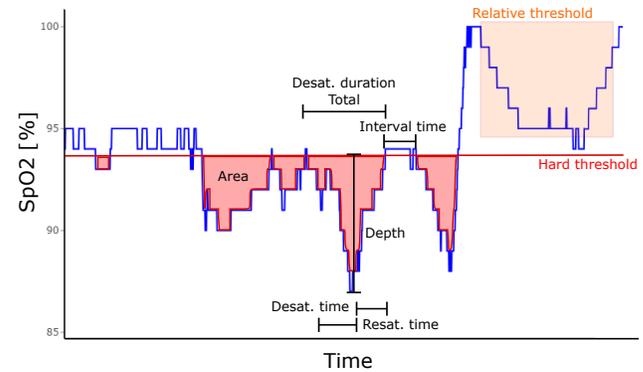

Fig. 1. Example of SpO₂ signal with desaturation parameters highlighted. Here the hard threshold is at 93% and the relative threshold is of 5%.

windows over the CO₂ signal, if the first one had no signal within it whereas the second one had only valid values within it, this was labeled as an event of transition to mechanical ventilation.

Oximetry biomarkers (OBMs). OBMs were extracted from the SpO₂ signal with a sampling frequency of 1Hz. As previously described by Levy et al.¹⁶, OBMs definitions are presented in Table S3. these biomarkers are divided into 5 categories: (1) General Statistics: time-based statistics describing the SpO₂ data distribution; (2) Complexity: quantifies the presence of long-range correlations in non-stationary signal; (3) Periodicity: quantifies consecutive events to identify periodicity in the SpO₂ signal; (4) Desaturations: time-based descriptive measures of the desaturation patterns occurring throughout the signal; (5) Hypoxic Burden: time-based measures quantifying the overall degree of hypoxemia imposed on the heart and other organs during the recording period.

Statistical Analysis.

Cohort. Comorbidities and demographics including age, weight, BMI, length of stay and death were collected. Comorbidities were defined by ICD-9 codes and analysed as by Benaim et al.¹⁰. A thorough analysis of comorbidities, demographics and mortality rate was performed to characterize predispositions for both the critical and non-critical group. Demographic variables and comorbidity rates, were compared between severity groups using the Chi-squared test or Fisher's exact test for categorical variables, and analysis of variance or Kruskal-Wallis test for continuous variables. The p-values across all tests were corrected to control the false discovery rate (FDR) criterion¹⁷. Medians and inter-quartile range (IQR) were used to describe the continuous variables.

SpO₂ global characteristics. The SpO₂ signal was summarised using a density of SpO₂ for each group of patients investigated. In addition, the SpO₂ density was computed per patient and support interval and was represented in a heatmap sorted by SpO₂ mean for each group.

Desaturation characteristics. In order to decide which desaturation definition was the most clinically relevant, we studied

the hypoxic burden as a function of each threshold (Figure 4A). The hypoxic burden was defined by the sum of areas of desaturations per hours for a given patient. The characteristics of the desaturation between each group were compared using the Wilcoxon test.

OBM comparisons across severity and support level. The OBM toolbox¹⁶ was used to extract OBMs from the SpO₂ signal using consecutive and non-overlapping windows of 1h. The average of each OBM per patient and under each support was computed for analysis. OBMs were used to discriminate between critical and non critical patients and characterize the effects of mechanical ventilation and oxygen support on the SpO₂ signal. The goal of this last analysis was to determine the influence of oxygen support or mechanical ventilation on the SpO₂ signal. Groups OBMs were compared using the Wilcoxon test.

OBMs and transition events. A sliding window of 30 minutes with a shift of 5 min was applied on the SpO₂ signal 8h before to 4h after transitions to study the dynamic of the signal and identify candidate OBMs anticipating a deterioration of the patient requiring intubation and mechanical ventilation. The median and the interquartile range of all transitions are represented for selected OBMs that depicted large variations before the transition.

The R software¹⁸ was used for statistical analysis. A significance threshold at 0.05 was used.

Results

Severe COVID-19 patients and hospitalisation course.

Patients were split into two groups based on disease severity with 162 critical and 205 non-critical patients (Table 1). Male patients were prevalent in both groups (60.5% in the non-critical group and 72.8% in the critical group). The in-hospital mortality was 38.9% in the critical group. The age distribution was significantly different (p-value < 0.05) with more patients 65-74 years old in the critical group and less patients 18-44 years old with respect to the non-critical group. The BMI distribution was balanced between groups. The length of stay (Table S1, Figure S3) was significantly longer in the critical group (p-value < 0.001, median non-critical = 5 days, median critical = 14 days). Patients in the critical groups had significantly more overall comorbidities (p-value = 0.01, Table 1, Table S2). Regarding vital signs at admission (Table S1), critical patients depicted a lower room saturation (SpO₂ measured breathing room air) and oxygen saturation (SpO₂ measured under oxygen support). The respiratory rate was significantly higher in the critical group indicating tachypnea.

Qualitative analysis of SpO₂ characteristics. A typical hospital course of a patient after admission is represented in Figure 2A. Hospitalized patients are monitored in the ward or in ICU. Qualitatively, the continuous monitoring of SpO₂

of a single patient depicted frequent small desaturations in a non-critical case, while a critical patient presented prolonged events of low SpO₂ (Figure 2B). The initiation of mechanical ventilation was visible on the EtCO₂ channel. The dynamics of the SpO₂ signal was noticeably impacted by mechanical ventilation, with a higher SpO₂ level and reduced variability (Figure 2C).

Quantitative analysis of SpO₂ characteristics.

SpO₂ distribution. The mean SpO₂ was significantly lower among critical patients without support, compared to the non-critical group (p-value < 0.05, 3A,C). The lower SpO₂ range between 80% and 90% depicted a higher density in the critical group (p-value < 0.01). The non-critical group showed a narrower peak of densities centered around 96% SpO₂. A similar, although milder trend was observed in the critical group versus non-critical patients by oxygen delivery devices (Figure 3B,C). The median oxygen flow rate used for the oxygen support was significantly higher in critical patients (p-value < 0.001). The use of mechanical ventilation reduced the density of low SpO₂ (80%-90%) to a level closer to that seen in non-critical patients. On the other hand, critically ill patients who were mechanically ventilated or on oxygen support depicted a higher density of SpO₂ level between 97% and 100% compared to critical non ventilated and non-critical patients. The SpO₂ density per patient in each group (Figure 3C) revealed the variety of SpO₂ patterns, notably in non-critical and critical patients without support. In addition, this analysis revealed that a sub-group of critical patients on oxygen support did not respond well to the therapy and thus subsequently required a mechanical ventilation support.

Desaturation analysis. Overall, based on the hypoxic burden (Figure 4A), the absolute threshold of 93% was the most discriminating between critical and non-critical groups with p-value < 0.001 and fold-change (FC) of 1.6 for no support and p-value < 0.05 and 2.9 FC under oxygen support. A relative threshold of 3% SpO₂ was able to discriminate critical from non-critical patients without support only (p-value < 0.001). Next, for the optimal definition (93% absolute), we compared the distribution of area, depth, and desaturation duration (Figure 1, Figure 4B) between the critical and the non-critical groups and with or without oxygen support. Interestingly, the non-critical group depicted more desaturations per hour compared to the critical groups (p-value < 0.05, FC 1.8). This difference was abolished by oxygen support (non-significant, NS). Similarly the depth and the "desat. time" of the desaturations were significantly more pronounced comparing the critical and non-critical groups when there was no support (p-value < 0.001, FC 1.35). This effect was not significant under oxygen support (NS). The only desaturation parameter that showed a significant difference between those groups under oxygen support was the desaturation area (p-value < 0.05, FC 1.6) consistent with what we observed looking at the hypoxic burden. Overall, the critical group showed a larger depth (p-value < 0.001, 1.23 FC), area (p-value < 0.001, 1.44 FC) and desat.time duration (p-value < 0.001, 1.35 FC) of the events

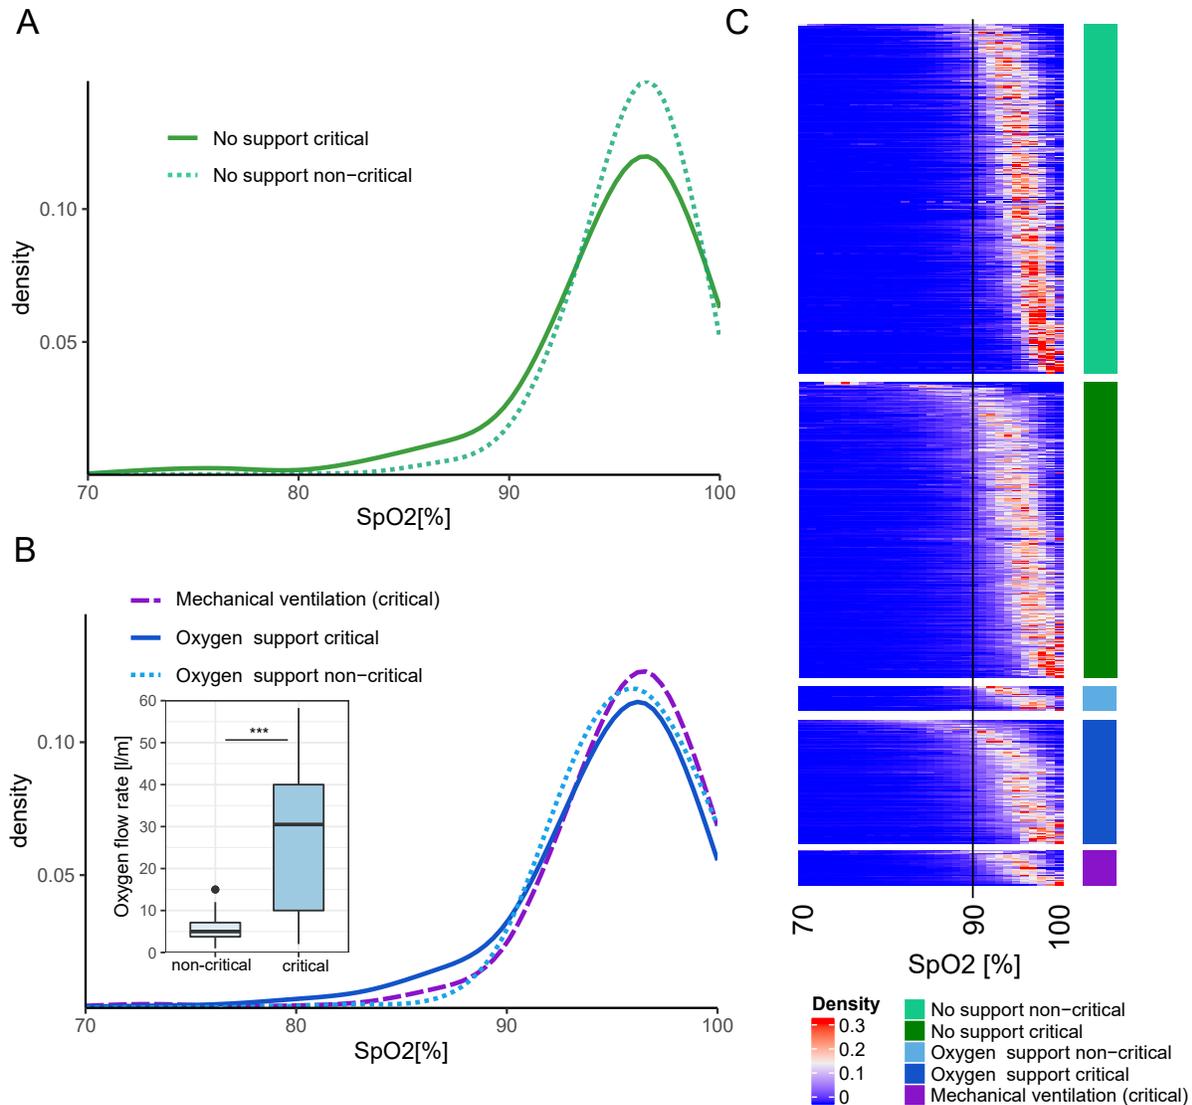

Fig. 3. Global characteristics of SpO2 signal. A) Density distribution of SpO2 for non-critical and critical patients without support. B) Density distribution of SpO2 from non-critical and critical patients for intervals under oxygen support or mechanical ventilation. The level of oxygen support (oxygen flow rate) was compared between non-critical and critical patients C) SpO2 density heatmap for each interval of SpO2 signal of patient in each group. A vertical black line represent the threshold of 90% SpO2 recommended in the WHO guidelines⁵ to identify severe patients.

with respect to the non-critical group. Oxygen support had a limited effect on the depth and the "desat. time", no significant differences between oxygen support and no-support were observed. Mechanical ventilation depicted a strong effect by significantly reducing the frequency of desaturations (p-value < 0.001, 1.85 FC) and the depth (p-value < 0.05, 1.21 FC).

Effect of treatment and OBMs. OBMs were investigated using a volcano plot analysis between the critical and non-critical groups without support (Figure 5A). OBMs definitions are presented in Table S3. OBMs related to hypoxic burden and desaturation depicted a large effect (log2 fold change) with highly significant p-values (large log10 p-

values) consistent with the preceding results. Remarkably, the integral of SpO2 below the 93% SpO2 (*CA93*) and the percentage of time below the 93% SpO2 (*CT93*, Figure S6) were the most discriminating OBMs. The same analysis under oxygen support (Figure 5B) revealed that most OBMs related to desaturation and hypoxic burden were not significantly different between the two groups apart from *CT93* and *CA93*. Overall, OBMs depicted reduced FDR adjusted p-values under oxygen support. However, general and periodicity related OBMs remained significantly affected between non-critical and critical group. Next, the effect of the support was investigated (Figure S5A-C). In non-critical patients the effect of oxygen support was mild (Figure S5A). Both FC and FDR adjusted p-values ranges were smaller than in the

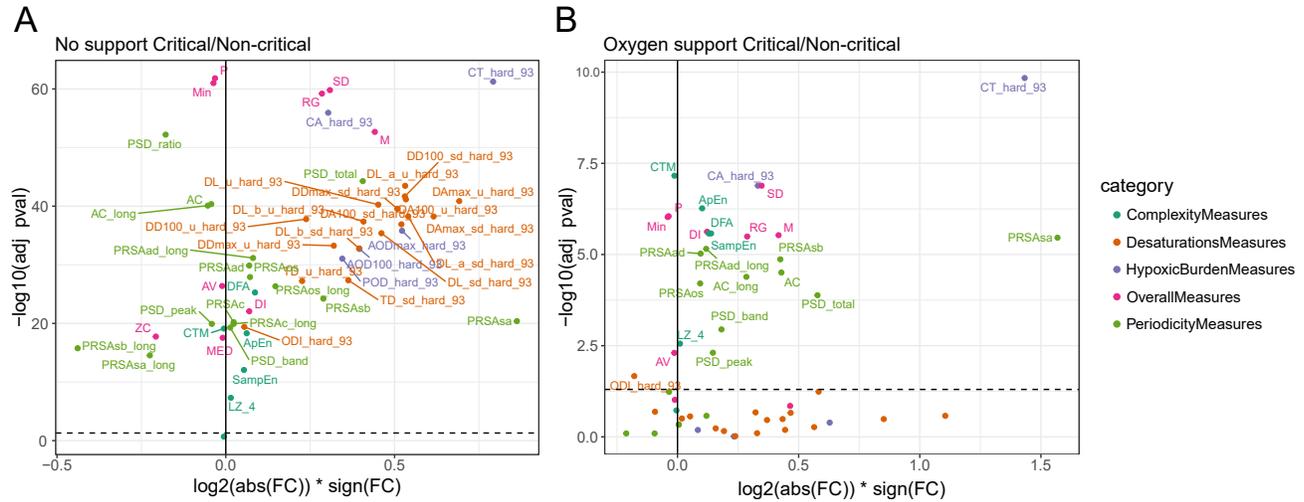

Fig. 5. OBMs across the spectrum of disease severity and treatment support. A) Critic versus non-critical without support and B) critical versus non-critical under oxygen support. OBMs definition are available in Table S3. See the Figure S5 for the comparisons between no-support and oxygen support or mechanical ventilation.

critical versus non-critical comparison (Figure 5A). OBMs related to hypoxic burden and desaturation parameters were still higher under oxygen support (Figure S5A). In the critical group under oxygen versus no support, the picture was similar indicating that the oxygen support had only a mild effect on OBMs (Figure S5B). On the other hand (Figure S5C), mechanical ventilation depicted a more pronounced effect on OBMs, notably with a reduction of all OBMs related to hypoxic burden, desaturation parameters, periodicity and complexity.

Transition analysis and OBMs' trajectory. There were a total of 43 patients with transitions, i.e. initiation of mechanical ventilation, with a total of 68 transitions overall. Among the patients that had transitions, they had a Q1 of 1, and a Q3 of 2 transitions, and the maximum number of transitions for a single patient was 3. Panel A of figure S4 shows examples of transition from three representative patients and panel B shows the average profile of every transition detected.

Temporal tracking of selected OBMs is illustrated in figure 6. The median SpO2 depicted a larger variation about 1h before the transition. The desaturation class represented by the *ODI93*, depicted large variations around the transition. The *ODI93* showed a decreased number about one hour and a half before the transition suggesting larger desaturations in agreement with *CA93* (hypoxic burden) showing an increase and a high variance before the transition. Approximate entropy *ApEn* (complexity) depicted a small reduction about 4 hours before the transition and marked decreased after the transition. Finally, *PSDtotal* (Periodicity) showed an increasing perturbation between 4 to 1-5 hours before the transition. Thus, the spectral band of interest (0.014–0.033Hz) appeared to have a greater power than the rest of the signal, before the transition.

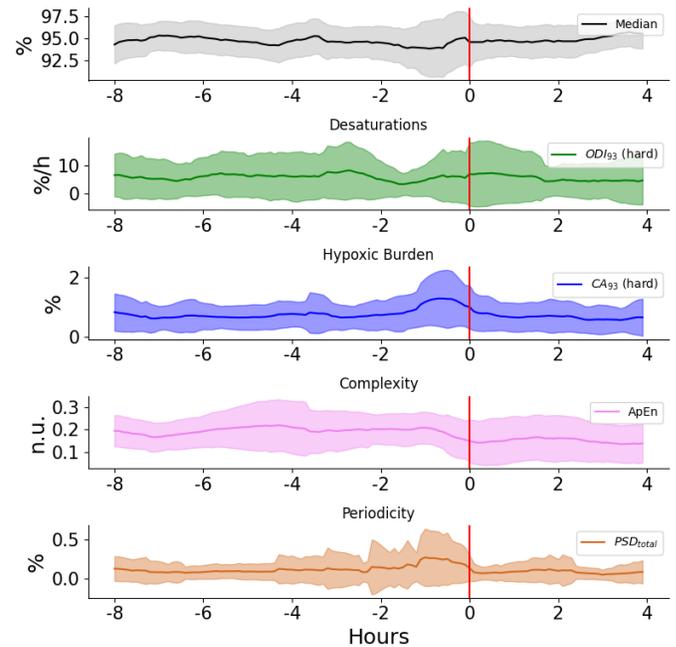

Fig. 6. Temporal tracking of OBMs before and after the initiation of mechanical ventilation. OBMs were computed using a sliding windows of 30 minutes, from 8 hours before the transition, to 4 hours after it with a shift of five minutes. The median and IQR were computed over 68 transition events. For each of the five category, one biomarker with low *p value* is represented. OBMs definition are available in Table S3

Discussion

Critical care medicine is complex, resource consuming and expensive. It is a dynamic and highly technical field of medicine treating the sickest patients. Decisions need to be made rapidly based on the evolving clinical state and the clinicians' interpretation of continuous physiological data¹⁹. The COVID-19 pandemic has amplified these challenges due to relative lack of medical personnel and the additional burden entailed by the need for patient isolation²⁰. Delays in

recognition of patient deterioration may lead to harm and even death. Decision support tools for patients monitoring appear crucial for early prediction of deterioration in patients with a respiratory disease caused by COVID-19. Pulse oximetry is routinely used for monitoring the patient's oxygen saturation level non-invasively²¹. A low oxygen level in the blood may entail reduced oxygen delivery to the tissues which can ultimately lead to organ failure. The oximetry has been widely used for the diagnosis/monitoring of respiratory pathologies, such as pulmonary edema, Acute respiratory distress syndrome (ARDS), pneumonia, obstructive sleep apnea (OSA)²²⁻²⁵, and more recently, in a research setting, for nocturnal chronic obstructive pulmonary disease (COPD) diagnosis²⁶. However, to our knowledge, no study investigated continuous high resolution SpO₂ characteristics (patterns and dynamics) in COVID-19 patients.

Patients with COVID 19 presenting to the emergency department go through meticulous investigation that includes physical examination, laboratory tests and continuous monitoring of vital signs^{27,28}. Depending on the results of this screening, the patient can be discharged or admitted for observation and treatment in a monitored or non-monitored bed. Oxygen support can be applied in case of hypoxaemia (SpO₂ < 94%, or a drop > 3% SpO₂) or in dyspnoeic patients with increased work of breathing who are at risk of respiratory failure²⁹. In more severe cases, the patient might be transferred directly to the ICU³⁰. If the patient shows signs of respiratory failure on admission or develops one later, they may be mechanically ventilated, or undergo an attempt of non-invasive support. Thus, multiple decisions are made by physicians in this process who need to factor both subjective observations and objective parameters such as SpO₂. However, how these decisions are made and what should be taken into consideration for increasing the level of care is not always clear³¹. Furthermore, there is a need to sort critical from non-critical patients and identify patients' status deterioration using non-invasive measurements. Pulse oximetry offers many advantages as it is a cost effective continuous monitoring method that can be used in hospital or in a telemedicine setting^{32,33}.

Our study aimed at describing SpO₂ characteristics along the treatment course of non-critical, critical with or without oxygen support and critically ill mechanically ventilated patients. While healthy people generally depict an oximetry in the range 94% to 98%³⁴, critical COVID-19 patients showed higher density of low SpO₂ (80%-90%) as compared to non-critical or critical ventilated patients (Figure 3). Thus several questions arise: what is an appropriate SpO₂ threshold to distinguish critical from non-critical patients? When should oxygen support and mechanical ventilation be initiated? How does ventilation and oxygen support affect the SpO₂ level and its dynamics? Several studies have started to investigate these questions. A recent study showed that a saturation below 90% correlates with a higher probability for mortality³⁵, but this work was based on discrete measures and not on continuous recording of SpO₂ and used death as an endpoint. Another recent investigation of SpO₂ and the ROX score at admission concluded that an SpO₂ below 78% was a good

predictor of mechanical ventilation requirement⁶ and that a ROX score above 1.4 while on non-invasive ventilation was a good predictor of failure. Other trials suggested that the ratio of SpO₂ to FiO₂ could serve as a non-invasive prognostic marker to facilitate early adjustment of treatment^{7,36}. In the present study, we motivated that a threshold of 93% best differentiates between critical and non-critical patients under no support or oxygen support. Thus, our work suggests a more stringent threshold compared to the WHO guidelines⁵ that define an operational threshold of 90% SpO₂ to define severe patients. In addition, a drop of 3% SpO₂ (relative threshold) was able to discriminate critical from non-critical patients without support. This is consistent with the recommendation of a prompt assessment in the emergency oxygen therapy guidelines²⁹ as it may indicate an acute deterioration in the patient's condition. In addition, our work highlighted the differences of SpO₂ dynamics between the critical and non-critical groups. Specifically, we observed that the non-critical group had frequent shallow desaturations, while critical patients had deeper and longer but less numerous desaturations (Figure 4). Our work also investigated the effect of the oxygen support, which drastically reduced the differences between the two groups. The effect of mechanical ventilation showed a reduction of the SpO₂ signal complexity, periodicity, a lower incidence of desaturation and a higher SpO₂ saturation level overall with a risk of over oxygenation potentially detrimental^{37,38}.

In addition, we have shown that various biomarkers and standard analysis of continuous oximetry formerly developed to study OSA or COPD^{16,22,26} may support the monitoring of COVID-19 patients. Strikingly, two OBMs related to the hypoxic burden class were most discriminative between critical and non-critical patients under no support or under oxygen support. These were: (1) the percentage of time below the 93% oxygen saturation threshold (CT93, Figure S6) (2) the integral of the signal below the 93% SpO₂ level normalized by the total recording time (CA93). This results was consistent with a recent study suggesting the cumulative oxygen deficit (COD) as a predictor of mechanical ventilation³⁹. The COD was defined as the difference of the areas under the reference (80mmHg) and the PaO₂-day curves. Next, we showed that continuous monitoring using OBMs could be informative for the prediction of transition events (initiation of mechanical ventilation). Combining these OBMs within a machine learning model may be beneficial to optimise the timing and the level of support to maximise the chance of recovery of patients.

Our study might have important clinical implications. First, it can serve as a tool to predict the patient's trajectory while being treated in the ward using oxygen supplementation or non-invasive ventilation (NIV). A number of scoring tools such as the ROX^{6,7} and P/F ratio⁴⁰ looking at respiratory variables, or the sequential organ failure assessment (SOFA)⁴¹ score or national early warning score 2 (NEWS2)⁴² have been examined. However no one has been validated in large scale studies, and they are usually measured or calculated on admission, or sporadically during hospital stay. SpO₂ monitoring

has the advantage of being used frequently and continuously in all patients requiring oxygen treatment, and the data can be saved and processed. Figuring out the appropriate time when escalation of therapy is required (i.e. intubate the patient) has been in debate since the start of the pandemic and still keeps occupying and concerning clinicians. We believe our study might shed light on this issue. Second, assessing oxygenation and desaturation patterns might serve as a prognostic tool in COVID 19 patients. Third, in an overwhelmed medical system, the decision whether to admit or discharge a patient to a ward or ICU is extremely important. Analyzing oxygenation can assist in that manner. Finally, our results can be relevant in other medical conditions involving the respiratory system such as pulmonary infections, COPD, ARDS and more. Large scale, preferably prospective randomized trials are required to validate our results.

The presented work has several important limitations. First, our work is a single center retrospective and descriptive study. Thus, there might have been a bias regarding which patients were monitored and the decision whether to initiate monitoring for a specific patient was not reasoned or recorded. Second, the EtCO₂ time-series were not analysed in depth beyond the detection of the initiation of the mechanical ventilation. Third, the level of FiO₂ was not used to further stratify patient's recorded intervals under oxygen support. In addition, we did not explore the effect of sub-type of support and other parameters such as PEEP or pressure support.

Conclusion

We provide the first report of continuous SpO₂ analysis in COVID-19 patients across severity categories and respiratory support levels. Continuous monitoring of SpO₂ is of paramount importance to characterize COVID-19 patients. Mechanical ventilation and oxygen support have an impact on the SpO₂ signal characteristics. Our work suggests using an absolute threshold of 93% of SpO₂ for the detection of clinically relevant desaturations. Finally, we have highlighted the possible benefit of other OBMs, such as the percentage of time below 93%, derived from raw continuous high resolution SpO₂ for improving the monitoring of COVID-19 patients.

Contributors

J.S., J.B., R.A., A.R.B., and D.E. were involved in the conception and design of the study. J.S. was the coordinator of the study. J.S., R.A., A.M. and A.R.B were responsible for the data collection. J.S. and J.B. wrote the first draft. J.S., J.L. and A.R.B. were in charge of the analysis. A.R.B and R.A. accessed and verified the data. All authors were involved in the interpretation, critically reviewed the first draft, and approved the final version.

Declaration of interests

The authors declare that there is no conflict of interest.

Data sharing

The anonymised database including the waveforms and the clinical data from the COVID-19 patients will be accessible upon reasonable request, which will be individually reviewed by the ethical committee of the Rambam HCC.

ACKNOWLEDGEMENTS

This research is partially supported by The Milner Foundation, founded by Yuri Milner and his wife Julia. We are grateful to the Placide Nicod foundation for their financial support (J.S.). We acknowledge the financial support of the Technion Machine Learning and Intelligent Systems center (MLIS). We would like to thank Prof. Pierre Singer for insightful discussion regarding the present work. We are grateful to the care team from the COVID-19 units of Rambam HCC.

Table S3. Oximetry derived biomarkers (OBMs) definitions adapted from levy et al. ¹⁶

Biomarker (OBMs)	Category	Definition	Unit
CA_hard_93	HypoxicBurdenMeasures	Integral of SpO2 below the x SpO2 level normalized by the total recording time, by default x=AV, here 93	%
CT_hard_93	HypoxicBurdenMeasures	Cumulative time below the x% oxygen saturation level normalized by the total recording time, by default x=90. here x=93	%
POD_hard_93	HypoxicBurdenMeasures	Time of oxygen desaturation event, normalized by the total recording time, by default x=3	s
AODmax_hard_93	HypoxicBurdenMeasures	The area under the oxygen desaturation event curve, using the maximum SpO2 value as baseline and normalized by the total recording time	%
AOD100_hard_93	HypoxicBurdenMeasures	Cumulative area of desaturations under the 100% SpO2 level as baseline and normalized by the total recording time	%
ODI_hard_93	DesaturationsMeasures	The oxygen desaturation index	event/h
DL_u_hard_93	DesaturationsMeasures	Mean of desaturations length	s
DL_sd_hard_93	DesaturationsMeasures	Standard deviation of desaturations length	s*s
DA100_u_hard_93	DesaturationsMeasures	Desaturation area: mean of desaturation area under the 100% SpO2 level as baseline	%*s
DA100_sd_hard_93	DesaturationsMeasures	Standard deviation of desaturation area under the 100% SpO2 level as baseline	%*%*s*s
DAmax_u_hard_93	DesaturationsMeasures	Desaturation area defined as the mean of the desaturation areas using the maximum SpO2 value in each desaturation event as baseline	%*s
DAmax_sd_hard_93	DesaturationsMeasures	Standard deviation of desaturation area	%*%*s*s
DD100_u_hard_93	DesaturationsMeasures	Mean of desaturations depth using 100% SpO2 level as baseline	%
DD100_sd_hard_93	DesaturationsMeasures	Standard deviation of desaturations depth using 100% SpO2 level as baseline	%*%
DDmax_u_hard_93	DesaturationsMeasures	Mean of desaturations depth	%
DDmax_sd_hard_93	DesaturationsMeasures	Standard deviation of desaturation depth	%*%
DS_u_hard_93	DesaturationsMeasures	Mean of the desaturation slope	%/s
DS_sd_hard_93	DesaturationsMeasures	Standard deviation of the desaturation slope	(%*%)/(s*s)
TD_u_hard_93	DesaturationsMeasures	Mean of time between two consecutive desaturation events	s
TD_sd_hard_93	DesaturationsMeasures	Standard deviation of time between two consecutive desaturation events	s*s
DL_a_u_hard_93	DesaturationsMeasures	Mean of length from the beginning of the desaturations to the lower point	s
DL_a_sd_hard_93	DesaturationsMeasures	Standard deviation of length from the beginning of the desaturations to the lower point	s*s
DL_b_u_hard_93	DesaturationsMeasures	Mean of length from the lower point of the desaturations to the end	s
DL_b_sd_hard_93	DesaturationsMeasures	Standard deviation of length from the lower point of the desaturations to the end	s*s
AV	OverallMeasures	Blood oxygen saturation (SpO2) mean	%
MED	OverallMeasures	SpO2 median	%
Min	OverallMeasures	SpO2 minimum	%
SD	OverallMeasures	SpO2 standard deviation	%
RG	OverallMeasures	SpO2 range	%
P	OverallMeasures	xth percentile SpO2 value, by default x=1	%
M	OverallMeasures	Percentage of the signal at least x% below median oxygen saturation, by default x=2	%
ZC	OverallMeasures	Number of zero-crossing points at the x% SpO2 level, by default x=AV	nu
DI	OverallMeasures	Delta index, by default x=12s.	%
PRSAc	PeriodicityMeasures	Phase-rectified signal averaging (PRSA) capacity. With d the fragment duration, here d=10	%
PRSAad	PeriodicityMeasures	PRSA amplitude difference. With d the fragment duration, here d=10	%
PRSAos	PeriodicityMeasures	PRSA overall slope. With d the fragment duration, here d=10	%/s
PRSAbs	PeriodicityMeasures	PRSA slope before the anchor point. With d the fragment duration, here d=10	%/s
PRSAas	PeriodicityMeasures	PRSA slope after the anchor point. With d the fragment duration, here d=10	%/s
AC	PeriodicityMeasures	Autocorrelation	%*%
PRSAc_long	PeriodicityMeasures	Phase-rectified signal averaging (PRSA) capacity. With d the fragment duration, here d=20	%
PRSAad_long	PeriodicityMeasures	PRSA amplitude difference. With d the fragment duration, here d=20	%
PRSAos_long	PeriodicityMeasures	PRSA overall slope. With d the fragment duration, here d=20	%/s
PRSAbs_long	PeriodicityMeasures	PRSA slope before the anchor point. With d the fragment duration, here d=20	%/s
PRSAas_long	PeriodicityMeasures	PRSA slope after the anchor point. With d the fragment duration, here d=20	%/s
PSD_total	PeriodicityMeasures	The integral of the power spectral density (PSD) function	%
PSD_band	PeriodicityMeasures	The integral of the PSD function within the band 0-0140-033Hz	%
PSD_ratio	PeriodicityMeasures	The integral of the PSD function within the band 0-0140-033Hz with respect to the total integral	nu
PSD_peak	PeriodicityMeasures	Peak amplitude of the PSD function within the band 0-0140-033Hz	%
ApEn	ComplexityMeasures	Approximate entropy with, by default, m=1, r=0.25 times the standard deviation of the data	nu
LZ	ComplexityMeasures	Lempel-Ziv complexity	nu
CTM	ComplexityMeasures	Central tendency measure with radius ρ, by default ρ=0.25	nu
SampEn	ComplexityMeasures	Sample entropy with, by default, m=1, r=0.25	nu
DFA	ComplexityMeasures	Detrended fluctuation analysis with, by default, n=20	%

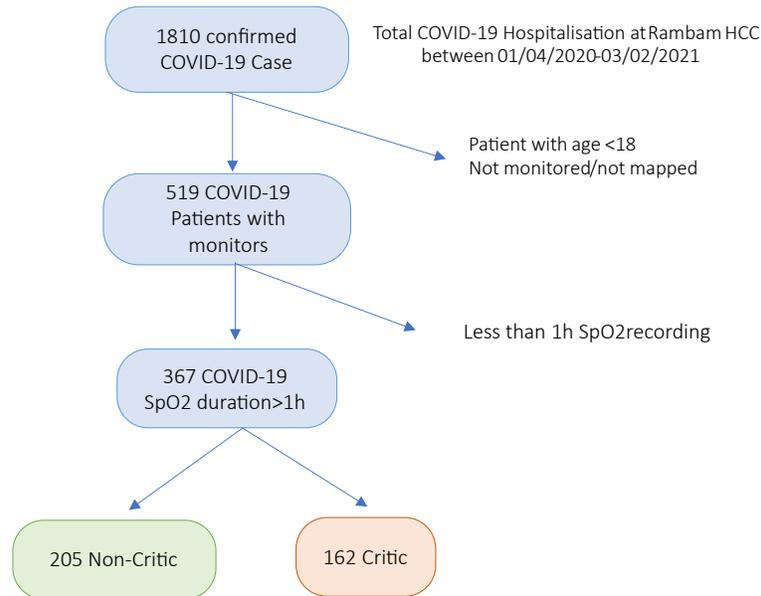

Fig. S1. Database content and selection criteria

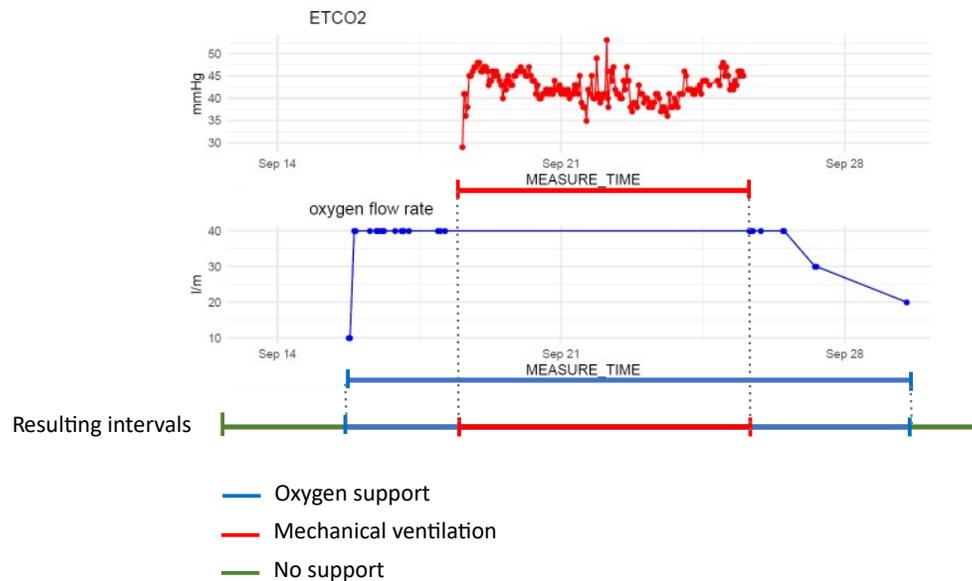

Fig. S2. Definition of oxygen support and mechanical ventilation intervals. The first and the last time stamp are used from the oxygen flow rate and from the EtCO₂ channel. No support is defined between the admission and the first information about support (or the last and the discharge) or if there is no support information, the whole monitoring is considered without support.

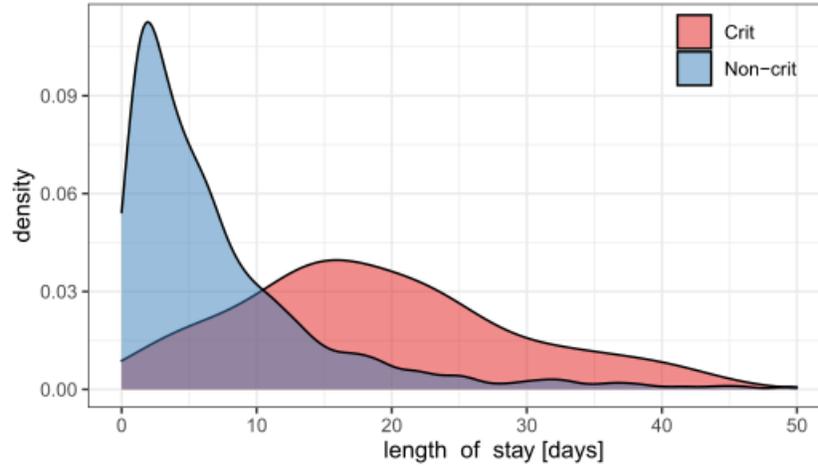

Fig. S3. Distribution of length of stay for critical (red) and non-critical (blue) COVID-19 patients.

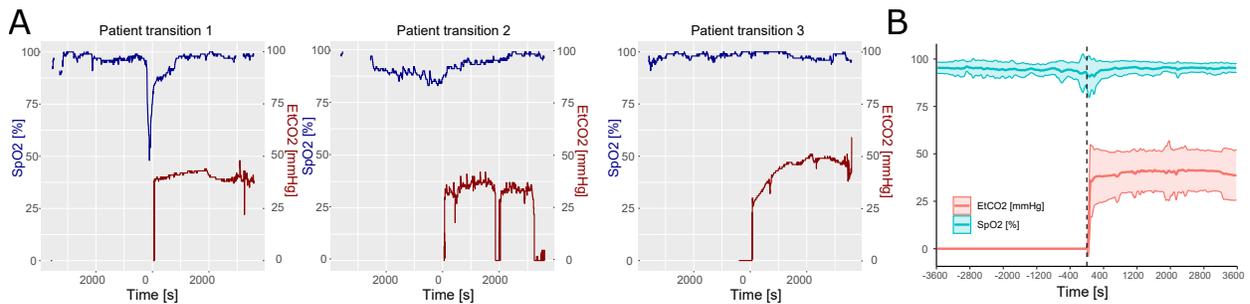

Fig. S4. Effect of the ventilation on SpO2 signal at the initiation of the ventilation. A) Representative initiation of ventilation in three different patients. EtCO2 (red) and SpO2 (blue) signal were extracted using 2h window centered on the ventilation initiation. B) Average and standard deviation of EtCO2 and SpO2 for all the detected transitions.

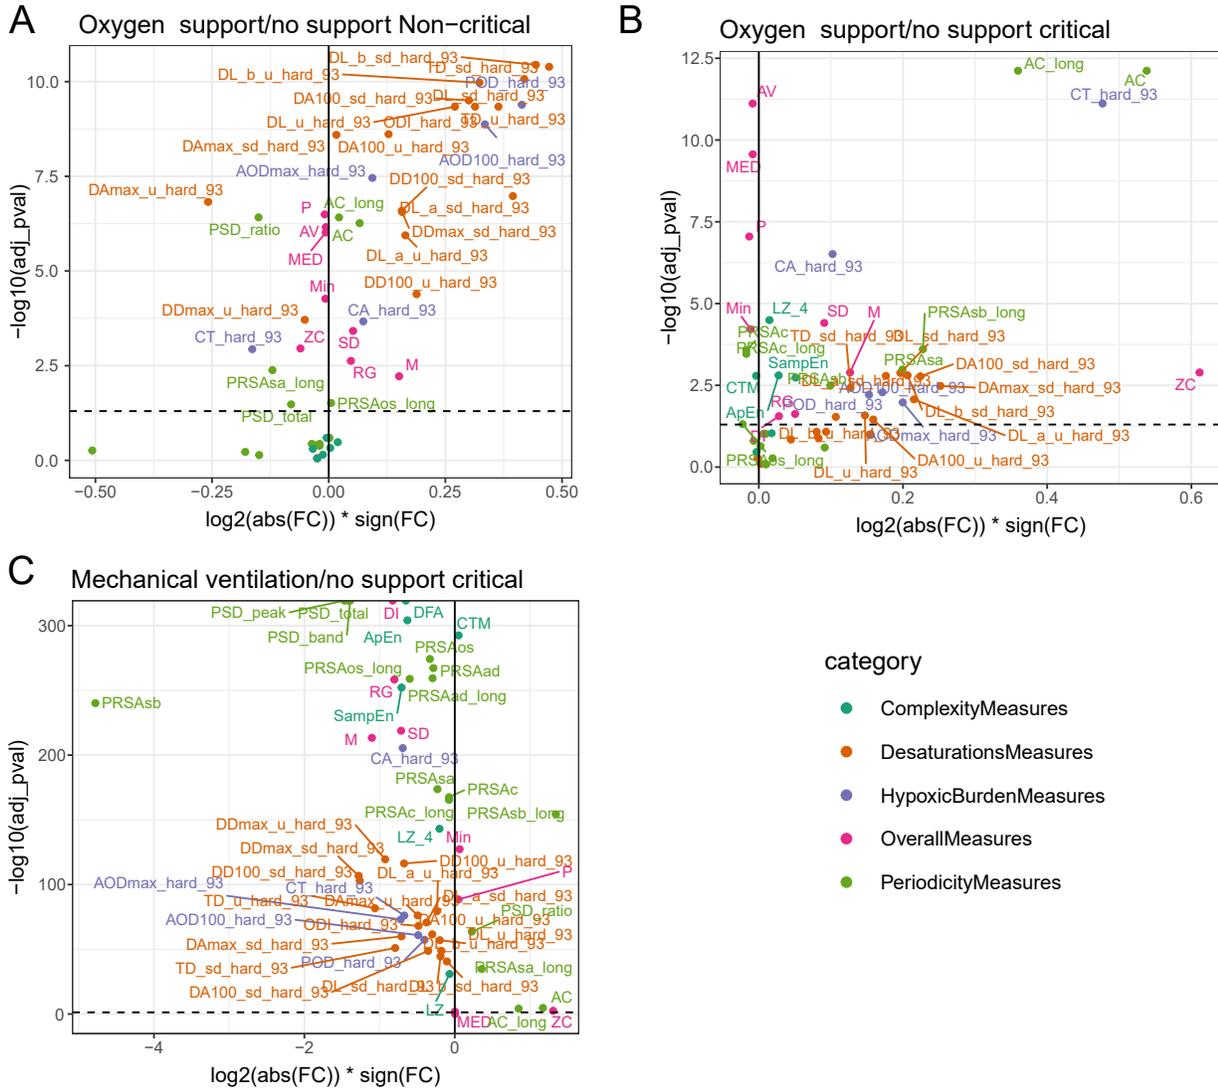

Fig. S5. OBMs across the spectrum of disease severity and treatment support. A) Non-critical under oxygen compared to non-critical without support. B) Critic under oxygen compared to critical without support. C) Critic under mechanical ventilation compared to critical without support. OBMs definition are available in Table S3

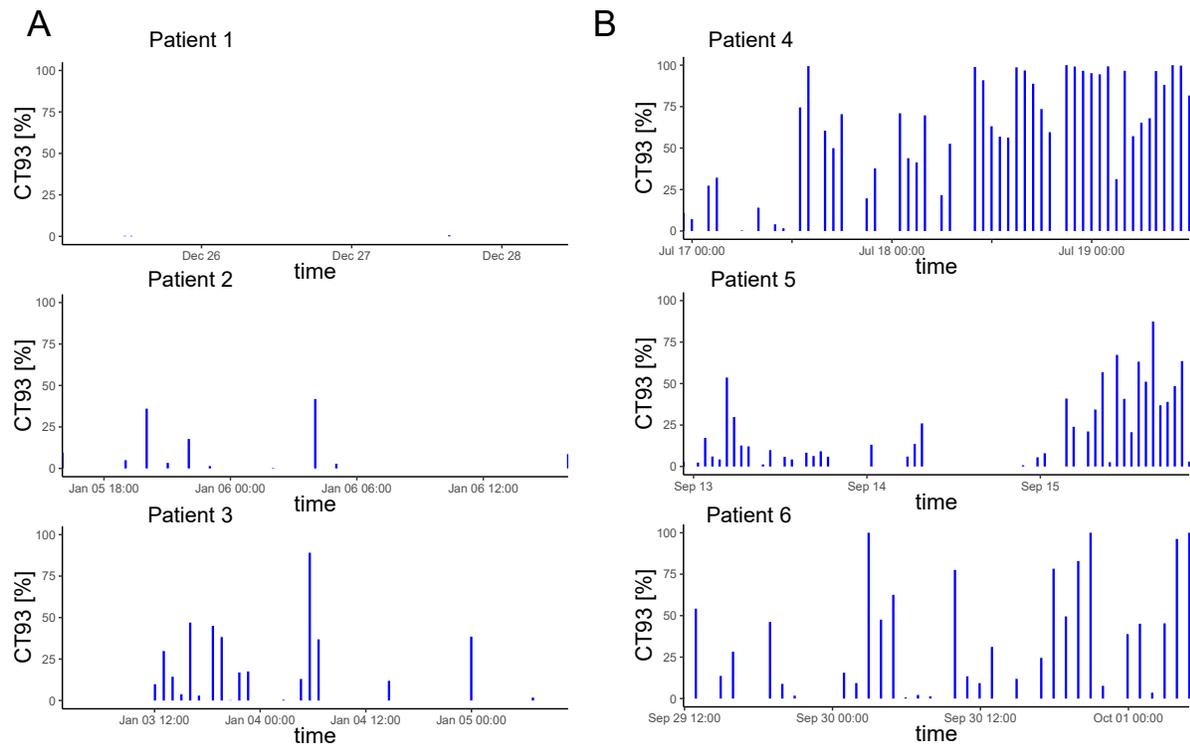

Fig. S6. OBM CT93, defined as the percentage of time under the 93% SpO₂ threshold, extracted from 1h windows for representative A) non-critical and B) critical patients without support. CT93 was the most discriminating biomarker between critical and non-critical group.
