Abstract

Background and hypothesis

Salience is a critical mechanism for animal survival. Aberrant salience is essentially implicated in psychosis, involving the midbrain–striatum–hippocampus and the anterior cingulate cortex (ACC)–insula salience network (SN) systems. However, whether these two systems jointly or independently contribute to psychosis traits, staging, and state remains unknown.

Study design

Eight scanners at seven institutions recruited 209 subjects with psychosis at the ultra-high-risk (UHR), first-episode (FEP), and chronic (ChrP) stages and 279 matched healthy controls (HC). Resting-state functional MRI data, which were intensively denoised and scanner effect-removed, revealed the two systems comprising five networks: midbrain-thalamic and striatal parts of the basal ganglia network (BGN-MbThal and BGN-Str), the medial temporal lobe network (MTLN), and the ACC and insular parts of the SN (SN-ACC and SN-Ins). Group differences, correlations with positive symptoms, and effects of medication/psychosis type of the networks were investigated in each psychosis stage.

Study results

Connectivity within the SN-ACC was reduced in UHR compared to HC (p<0.05, family-wise-error [FWE] corrected) and in the FEP and ChrP stages at liberal thresholds, with effect sizes of UHR>FEP>ChrP. FEP showed reduced connectivity within the BGN-MbThal, increased brain-state instability among the five networks, and positive correlations between

positive symptoms and connectivity within and between the MTLN (all p<0.05, FWE). The correlation was stronger in unmedicated than in medicated, and in affective than in non-affective psychosis patients (p<0.05, FWE).

Conclusions

The results provide a novel concept that the two salience mechanisms work in an integrated and separate manner in psychosis.

Key words: aberrant salience hypothesis, hippocampus, midbrain, salience network, striatum, thalamus

Main text

Introduction

Salience denotes being particularly noticeable or important, and is computationally defined as the absolute value of the prediction error [1] and the Laplacian of stimuli [2]. For survival, animals must quickly allocate their limited attentional resources to salient stimuli in the surrounding world. Previous animal studies showed that midbrain-striatal dopaminergic activity codes motivational (reward and avoidance) salience[3–5], whereas human functional magnetic resonance imaging (fMRI) studies showed that the striatum is responsive to stimulus salience[6–9].

Alterations in the midbrain-striatum region are indicated in psychosis[10], most commonly schizophrenia[11]. Elevated dopamine levels in the striatum of patients with schizophrenia[12] have been hypothesized to cause aberrantly heightened salience attribution to ordinary stimuli, leading to delusions and hallucinations; i.e. positive symptoms[13] (aberrant salience hypothesis)[10]. Additionally, recent circuit models of psychosis indicate that hippocampal overactivity triggers a hyperdopaminergic state in the midbrain and striatum[14]. These findings were consistent with those of recent clinical studies[15,16]. Thus, the midbrain-striatum-hippocampus system plays a critical role in aberrant salience in psychosis.

Human fMRI studies have described another neural system, the salience network (SN), which mainly comprises the anterior cingulate cortex (ACC) and bilateral insula and is activated by the salience of stimuli rather than the nature of tasks[17,18]. Recent studies have implicated SN alterations in psychotic symptoms and schizophrenia[19–23]. However, a critical unanswered question is the role of the ACC-insular SN system in the aberrant salience of psychosis. Alternatively, do these two salience-related systems contribute to aberrant salience either jointly or differently?

Recently, the SN is included in the "triple network model", which postulates that the SN act as a switching-hub between the default mode network (DMN) that is activated during rest/introspection, and the frontoparietal network (FPN) that is activated on task/cognitive effort[24,25]. Dysfunction of the triple network is associated with various psychiatric disorders, including psychosis[26–29]. However, elucidating the pathophysiology of aberrant salience in psychosis requires consideration of the two neural systems directly related to salience per se. To date, no study has done so.

Resting-state fMRI (rsfMRI) is widely used to investigate the functional connectivity of brain networks in patients with psychiatric disorders. Independent component analysis (ICA) of rsfMRI can identify large-scale networks representing the midbrain-striatum-hippocampus and ACC-insular SN systems in a data-driven manner; the midbrain and striatum were identified as the basal ganglia network (BGN[30]), the bilateral hippocampus was identified within the medial temporal lobe network (MTLN[31], also known as meso/paralimbic network[32]), and the SN comprised the ACC and insula[17]. Investigating the connectivity within and between these three networks can answer the questions above.

Biomarkers for psychosis/schizophrenia are essentially needed. Biomarkers are generally categorized as 1) trait markers, which are present throughout the disease course and are not changed by treatment; 2) staging markers, which are prominent in certain disease stages; and 3) state markers, which reflect symptoms and changes according to the treatment[33–36]. The course of psychosis can be divided into ultra-high-risk (UHR), first-episode (FEP), and chronic (ChrP) psychosis stages[37]. Whether aberrant salience is associated with psychosis traits, stage, or state is unclear, although dopaminergic dysfunction is reportedly more marked in FEP than in UHR[38].

Thus, we investigated how the two salience-related systems are associated with the aberrant salience of psychosis using ICA of rsfMRI. Our main outcome was whether

functional connectivity within and between the BGN, MTLN, and SN was associated with the 1) diagnosis of psychosis and/or 2) positive symptom severity at the UHR, FEP, and ChrP stages. The secondary outcomes were whether antipsychotic medication and psychosis type (affective or non-affective psychoses) affected the findings of 1) and 2), to further clarify the findings. To fully describe the connectivity profile, we investigated two complementary aspects of static (temporally constant across the time-course)[39] and dynamic[40] (temporally varying during the time-course) network measures. Considering that marked dopaminergic dysfunction in FEP and the effects of antipsychotics (dopamine blockers) on positive symptoms, we hypothesized that the midbrain-striatum-hippocampus system would be associated with positive symptoms as well as medication, especially in FEP.

Methods

Participants

The details are described in the Supplemental Methods and Supplemental Tables S1−S7 in the Supplemental Material. We recruited 488 individuals with UHR, FEP, and ChrP and matched healthy controls (HC) from eight scanners at seven institutions (Table 1). Hereafter, we refer to individuals with UHR as "patients" to refer to UHR, FEP, and ChrP as a whole.

The medication status (unmedicated or medicated) and psychosis type (affective or non-affective) of FEP were partially unbalanced, while those of ChrP were unbalanced.

After receiving a complete description of the study, all participants provided written informed consent. The study design was approved by the following institutional review boards of each institution:
approved by Hammersmith Hospital Research Ethics Committee (IoPPN);
approved by Johns Hopkins Medicine Institutional Review Board (JHM IRB) (JHU);

approved by Research Ethical Committee of Kanazawa Medical University (KMU);

approved by Kyoto University Graduate School and Faculty of Medicine, Ethics Committee

(Kyoto);

approval by Research Ethics Committee, Osaka University (OSK);

approved by Research Ethics Committee of the Faculty of Medicine of the University of

Tokyo (Tokyo);

and approved by Ethics Committee, University of Toyama (TYM).

MRI acquisition

The details are provided in Supplemental Methods and Supplemental Table S8.

Preprocessing

The details are provided in the Supplemental Methods, Supplemental Table S9, Supplemental

Figures S1 and S2, and Supplemental Video S1. In addition to conventional preprocessing

steps, ICA-based denoising[41] was performed to intensively remove non-neuronal noise from

the rsfMRI data.

As an index of data quality, the temporal signal-to-noise ratio (tSNR) was calculated

at each voxel as the mean/SD of the time course and was averaged for the whole brain using

QAscript[42].

Meta-ICA to identify group-level networks

We performed meta-ICA[43,44], which has higher robustness and reproducibility for group-level

network identification than conventional single-shot group ICA[45]. The details are described in

the Supplemental Methods.

Network identification

After meta-ICA, the networks of interest (NOIs: the BGN, SN, and MTLN) were identified (Supplemental Methods, Supplemental Figure S3, and Supplemental Table S10). The BGN and SN were split into two parts, for a total of five NOIs (Figure 1a).

Thresholded dual regression

Details are in provided in the Supplemental Methods. After meta-ICA, individualized spatial maps and time courses of each network were obtained using thresholded dual regression[46] to more accurately estimate the time courses of networks than conventional dual regression[47]. Spatial maps of the five NOIs were used for static within-network connectivity analysis. For static between-network connectivity, Z-transformed partial correlations between the time courses of the NOI-pairs were calculated while controlling for the other three NOIs.

Dynamic analysis by ELA

We performed dynamic[40] analysis using energy landscape analysis (ELA)[48–53] (Supplemental Methods), which estimated an "energy landscape" with two stable brain states from activity patterns of the time courses of the NOIs obtained above. States A and B were characterized by "all-NOIs-deactivated" and "all-NOIs-activated" patterns, respectively (Figure 1b and 1c). Then, two indices of the frequency and transition rate of the brain states were calculated for each participant.

Site/scanner effect harmonization

Although multi-site, large sample-size studies can increase reproducibility[54], site/scanner difference substantially affects their results[55–57]. Thus, we estimated and removed additive and multiplicative site/scanner effects using ComBat [58–60], which can also effectively harmonize

unbalanced data[59]. The details are provided in the Supplemental Methods. Supplemental Figure S4 illustrates efficient removal of the site/scanner effect.

Statistical analysis

Details are provided in the Supplemental Methods. Permutation-based non-parametric inference[61] was used to perform 1) group comparisons between patients and HC and 2) multiple regression analyses with positive symptom severity, for within- and between-network connectivity and ELA indices at each psychosis stage. Age, sex, and mean tSNR were covariated. The statistical threshold was $p < 0.05$, family-wise error (FWE) corrected for the number of voxels, contrasts, and five networks/10 network pairs/two ELA indices. We also reported at more liberal thresholds ($p < 0.1$, FWE for voxels, contrasts, and networks/network pairs/indices and $p < 0.05$, FWE for voxels and contrasts).

Effects of medication and psychosis type

We then investigated the effect of medication status and psychosis type on significant group differences and correlations, as described in the Supplemental Methods. In the case of FEP, since Johns Hopkins University (JHU) includes both medication status and psychosis types, we additionally performed the same analyses for this site only.

Effects of comorbidity, smoking, and substance use

We investigated the effects of comorbidities, smoking, and substance use (Supplemental Methods).

Results

1) Demographic data

The details of Table 1 are described in the Supplemental Results.

2) Main outcome 1: group comparisons

Compared to the HC, we observed significant connectivity reductions within the ACC part of the SN (SN-ACC) in UHR, and within the midbrain-thalamus part of the BGN (BGN-MbThal) in the right thalamus in FEP (p = 0.003 and 0.02, respectively; FWE corrected for voxels, contrasts, and networks) (Figure 2a). At more liberal thresholds, the SN-ACC showed a reduction in FEP (p = 0.07, FWE for voxels, contrasts, and networks) and ChrP (p = 0.04, FWE for voxels and contrasts) at almost the same locations as in UHR (Figure 2b). The effect sizes of these clusters for UHR, FEP, and ChrP were 1.45, 0.60, and 0.54, respectively (Figure 2c)[62]. Other results at liberal thresholds are shown in Supplemental Figure S5.

Between-network connectivity did not differ at any stage, even at liberal thresholds.

ELA revealed a significantly increased transition between the two brain states in FEP (p = 0.003, FWE for contrasts and indices) (Figure 2d). No other significant differences were observed even at liberal thresholds.

3) Main outcome 2: correlational analyses

We observed a significant positive correlation between positive symptom severity (positive scale of Positive and Negative Syndrome Scale [PANSS][63]) and connectivity within the MTLN in the left/right hippocampus and parahippocampal gyrus in FEP (p = 0.03 and p = 0.02 for the left and right, respectively; FWE for voxels, contrasts, and networks) (Figure 3a and 3b). Figure 3c shows no clear site/scanner effects. Supplemental Figure S6a shows the

results at liberal thresholds. No other significant correlations were observed.

A significant positive correlation was also found between the PANSS positive scale and connectivity between the MTLN and BGN-MbThal in FEP (p = 0.04, FWE for contrasts and network pairs) (Figure 3d). Figure 3e shows no clear site/scanner effects. Supplemental Figure S6b shows results at liberal thresholds for UHR and FEP. No other significant correlations were observed.

The ELA indices did not show significant correlations with positive symptoms even at liberal thresholds.

4) Secondary outcome 1: effect of medication

We did not find any significant effect of antipsychotic medication on group comparison results (Supplemental Results).

The regression coefficients between the PANSS and the mean cluster value of the MTLN were significantly larger in unmedicated patients than in medicated patients, both for all sites and JHU alone (p = 0.009 and p < 0.001, respectively, FWE for contrasts. Figure 4a top row).

The regression coefficients between PANSS and the connectivity between the MTLN and BGN-MbThal were also significantly larger in unmedicated patients than in medicated patients for all sites and JHU alone (p = 0.01 and p < 0.001, respectively; FWE for contrasts. Figure 4a, bottom row).

5) Secondary outcome 2: effect of psychosis type

We did not find a significant effect of psychosis type on group differences (Supplemental Results).

The regression coefficient between the PANSS positive scale and the mean cluster value of the MTLN was significantly larger in affective than in non-affective psychosis patients, both for all sites and JHU alone (p = 0.003 and p < 0.001, respectively; FWE for contrasts. Figure 4b, top row).

The regression coefficient between PANSS and the connectivity between the MTLN and BGN-MbThal was also significantly larger in affective than in non-affective psychosis patients for all sites and JHU alone (p = 0.001 and p < 0.001, respectively; FWE for contrasts. Figure 4b, bottom row).

6) Sensitivity analyses of the main and secondary outcomes

While a patient with the highest connectivity value in Figure 3 may appear to be an outlier, Cook's distance (<0.5) indicated that this was not the case, and our permutation-based non-parametric inference was robust against outliers. However, we performed two sensitivity analyses: 1) excluding this participant and 2) using Spearman's rank correlation (details in the Supplemental Results).

Excluding this patient did not affect the correlations with PANSS. The effect of medication on the within- and between-network correlation analyses showed trend-level significance, whereas the effects of psychosis type disappeared (all FWE for contrasts).

Spearman's rank correlation revealed that the within- and between-network correlations with PANSS and the effect of medication on the between-network correlation remained significant, while other secondary analyses were not significant (all two-tailed).

7) Effects of comorbidity, smoking, and substance use

Comorbidity, smoking, and substance use did not affect any of the significant group

difference results (Supplemental Results).

The effect of comorbidity on the regression coefficients between the PANSS positive scale and the connectivity of the MTLN showed a trend-level significance for within-network connectivity (Supplemental Figure S7) and fully corrected significance for between-network connectivity (Figure 4c) (p = 0.08 and 0.03, respectively; FWE for contrasts). Sub-analysis of the latter showed a trend-level positive correlation in patients without comorbidity and no correlation in patients with comorbidity (p = 0.06 and 0.279, respectively; FWE for contrasts). These findings indicated that the correlational findings were specific to psychosis rather than common among psychiatric disorders[64].

Smoking showed trend-level effects on the correlations between PANSS and within- and between-connectivity of the MTLN (Supplemental Results and Supplemental Figure S8).

Substance use did not affect the correlation between connectivity and PANSS scores (Supplemental Results).

Discussion

The main findings of this study were:

1: Reduced within-network connectivity and increased instability of the two salience-related systems in UHR and FEP, with the SN showing significance levels and effect sizes in the order UHR > FEP > ChrP.

2: Association between severer positive symptoms and stronger connectivity within and between the midbrain-striatum-hippocampus system in FEP.

3: Attenuation of finding 2 in medicated or non-affective psychosis patients.

Collectively, we found fully corrected significance in UHR and FEP but not in ChrP, indicating that aberrant salience is more "salient" in early stages of psychosis[65].

Salience-related functional measures represent psychosis traits/staging

Regarding the midbrain-striatum-hippocampus system, we observed reduced connectivity in the thalamus of the BGN in patients with FEP. We recently reported heightened resting connectivity between the thalamus and cortical areas in patients with FEP[66] in a sample that partially overlapped with the present study. Moreover, the thalamus has recently been reported to process salience[67]. Thus, the current results extend our knowledge of the underlying structure of aberrant salience in psychosis. In contrast, we did not observe altered within-network connectivity in the striatum of the BGN, whereas two previous ICA studies reported increased within-network connectivity[68,69]. Compared to these studies, we thoroughly considered confounding factors and strongly controlled for multiple comparisons.

For the ACC-insular SN system, we observed reduced within-network connectivity, with significance levels and effect sizes in the order of UHR > FEP > ChrP, in almost the same locations in the ACC (Figure 2b). This finding indicates that SN alterations are present at an early stage and may be weakened by chronicity. These findings are also largely consistent with those of previous ICA studies reporting reduced within-network SN connectivity in patients with schizophrenia [70–74].

This is the first ELA study to reveal frequent transitions between two brain states; that is, increased instability of salience-related networks in FEP. Previous studies have reported increased instability in the SN, FPN, and DMN in schizophrenia, consistent with our findings[75,76]. The finding of synchronized activation/deactivation patterns of all five NOIs in the two brain states is consistent with our view that the integration of different salience systems plays a key role in the pathophysiology of psychosis[77].

Importantly, these findings were not affected by medication, psychosis type, comorbidities, smoking, or substance use. Therefore, the within-network connectivity and brain-state transition of the two salience-related systems are candidates for early-stage

markers of psychosis; moreover, the ACC-insular SN system may also serve as a trait marker.

Midbrain-striatum-hippocampus functional connectivity represents a psychosis state

We observed significant associations between more severe positive symptoms and stronger functional connectivity within the MTLN and between the MTLN and BGN-MbThal only at the FEP stage. These findings are consistent with the current view that pathophysiological changes are most drastic at this stage[37,38], especially in the hippocampus[78]. To date, no study has investigated the MTLN in psychosis using rsfMRI and ICA; thus, our findings are not only new but also important, as the hippocampus is postulated to be the starting point of dopaminergic aberrant salience in psychosis[14]. The midbrain region of the BGN-MbThal was also associated with positive symptoms, although at a liberal threshold (Supplementary Figure S6a).

Importantly, these associations were attenuated in medicated patients, consistent with the requirements for state markers[34,35]. Moreover, this association was stronger in patients with affective psychosis than in those with non-affective psychosis. Since affective psychosis has better treatment responsiveness than non-affective psychosis[79], these findings may represent responsiveness to antipsychotic medications. The finding that these associations were weakened by comorbidity and possibly smoking is not contradictory to this state-marker view.

We did not observe an association between positive symptoms and connectivity of the ACC-insular SN system at a fully corrected level, although we did observe associations at liberal thresholds (Supplementary Figure S6b). Taken together, these findings suggest that the functional connectivity of the midbrain-striatum-hippocampus system is a candidate state marker for aberrant salience, more so than the ACC-insular SN system.

Robustness of the findings

A recent study reported that standard rsfMRI analysis with non-individualized cortical parcellation, without denoising, and without site/scanner-effect harmonization would require thousands of participants to attain statistical significance[80]. Our current findings, using ICA-based denoising, robust estimation of individualized large-scale networks by meta-ICA and thresholded dual regression, and harmonization by ComBat, were robust against full multiple comparison corrections. ComBat also efficiently harmonized the imbalance of medication status and psychosis type among our data, consistent with a previous report[59].

The sensitivity analyses may indicate that the effect of medication is more robust than that of psychosis type or may be due to the smaller sample size in the latter (20 for unmedicated status while 13 for affective psychosis).

Limitations

This study has several limitations. First, owing to the relative difficulties in recruiting UHR individuals and organizing a multi-site study, the UHR sample size was smaller than that of the FEP and ChrP. Second, susceptibility-induced distortion correction was not performed because several sites did not have the field maps required for this procedure. Third, while a longitudinal study design is more suitable, covering all stages is unrealistic, as it would require at least10 years of follow-up using the same scanner. Finally, developing clinically usable biomarkers from our findings will require their translation into more standardized frameworks, such as the estimation of individualized networks using the Bayesian approach with big-data population priors[81], individualized cortical parcellation[82], and/or combination with other modalities[66,83–85].

Conclusions

Functional alterations of the two salience-related systems, the midbrain-striatum-hippocampus and ACC-insular SN systems, were mainly associated with the early stages of psychosis. Alteration of the latter might be associated with psychosis traits, while the former was associated with the psychosis state, reflecting both positive symptoms and antipsychotic treatment. Further refinement of these findings will help to realize precision psychiatry. Our results provide a novel concept, stating that the two salience mechanisms work in both integrated and separate manners in psychosis.

* p<0.05

** p<0.001

a: No significant difference between PT and HC unless otherwise indicated.

b: Completed years of education were significantly shorter in UHR (t=2.4, df=51, p=0.02), FEP (t=5.1, df=185, p<0.001), and ChrP (t=6.5, df=238, p<0.001) groups than in HC group.

c: Information about smoking is available from the IoPPN, JHU, Kyoto, OSK, and Tokyo sites. There were more current smokers in the FEP group than in the HC group (chi-square=12.5, df=1, p=0.001 by Fisher's exact test).

d: Subjects from Japanese sites had no experience with substance use. There were more substance users in the FEP PT group than in the HC group (chi-square=10.6, df=1, p=0.002 by Fisher's exact test).

e: CAARMS positive scores were available for 26 UHR PT.

f: PANSS positive scores were available for 76 FEP and 94 ChrP PT.

g: One UHR subject was administered 50 mg of quetiapine. Medication dose information was available for 55 FEP patients and 72 ChrP patients.

Abbreviations

CAARMS, Comprehensive Assessment of At-Risk Mental States; ChrP, chronic schizophrenia; CP eq, chlorpromazine equivalent; DOI, duration of illness; F, female; FEP, first-episode psychosis; HC, healthy control; UHR, high risk; IoPPN, Institute of Psychiatry, Psychology and Neuroscience; JHU, Johns Hopkins University Hospital; KMU, Kanazawa Medical University; M, male; Med, medicated; N, no; OSK2, scanner number 2 of Osaka University; OSK3, scanner number 3 of Osaka University; PANSS, positive and negative syndrome scale; PT, patients; Tokyo, The University of Tokyo; tSNR, temporal signal/noise ratio; TYM, Toyama University; Unmed, unmedicated; Y, yes.

Figure legends

Figure 1. Networks of interest (NOIs) characteristics.

a) Meta-ICA identified the midbrain-striatum-hippocampus system as the MbThal and Str

parts of the BGN and the MTLN. The SN system was identified as the ACC and Ins parts.

The hierarchical clustering is shown on top.

b, c) Energy landscape analysis aggregated the time course patterns of the NOIs into two

brain states. In the local minima (low-energy, frequent pattern) of state A, five NOIs were

"deactivated" (below the mean time-course) in synchronization, but were "activated" (above

the mean) in state B.

Abbreviations

ACC, anterior cingulate cortex; BGN, basal ganglia network; ICA, independent component

analysis; Ins, insula; MbThal, midbrain and thalamus; MTLN, medial temporal lobe network;

SN, salience network; Str, striatum.

Figure 2. Group comparisons.

a) Reduced within-network connectivity in UHR and FEP. b) The significance level of the SN

was UHR > FEP > ChrP.

Yellow/*** $p < 0.05$, family-wise error (FWE) corrected for voxels, contrasts, and networks.

Orange/** $p < 0.1$, FWE for voxels, contrasts, and networks.

Red/* $p < 0.05$, FWE for voxels and contrasts.

Light blue: NOIs.

c) The effect size of the ACC was UHR > FEP > ChrP.

d) Increased transition between brain states in FEP.

p < 0.05, FWE for contrasts and ELA indices.

Abbreviations

ACC, anterior cingulate cortex; BGN, basal ganglia network; ChrP, chronic schizophrenia; ELA, energy landscape analysis; FEP, first-episode psychosis; HC, healthy controls; Ins, insula; MbThal, midbrain and thalamus; MTLN, medial temporal lobe network; NOI, network of interest; PT, patients; SN, salience network; Str, striatum; UHR, ultra-high-risk for psychosis.

Figure 3. Correlational analysis results in FEP (n=76).

a) Positive correlation between PANSS positive scale and the connectivity within the MTLN.

Yellow/*** p < 0.05, family-wise error (FWE) corrected for voxels, contrasts, and networks.

Orange: p < 0.1, FWE for voxels, contrasts and networks.

Light blue: MTLN NOI.

b) Scatter plot of a).

c) No clear site/scanner effect.

d) Positive correlation between the PANSS positive scale and connectivity between the MTLN and BGN-MbThal.

*** p < 0.05, FWE for contrasts and network-pairs.

e) No clear site/scanner effect.

For b) – e), the PANSS and connectivity values were adjusted for age, sex, and tSNR.

For the site/scanner names c) and e), please refer to Table 1.

Abbreviations

BGN, basal ganglia network; Btw, between; FEP, first-episode psychosis; MbThal, midbrain and thalamus; MTLN, medial temporal lobe network; NOI, network of interest; PANSS, Positive and Negative Syndrome Scale; tSNR, temporal signal-to-noise ratio.

Figure 4. Effect of medication, psychosis type, and comorbidity.

All $p < 0.05$, FWE for contrasts. The PANSS and connectivity values were adjusted for age, sex, and tSNR.

a) Larger regression coefficients between the PANSS positive scale and MTLN connectivity in unmedicated patients than in medicated patients.

Upper row: connectivity within the MTLN.

Bottom row: connectivity between the MTLN and BGN-MbThal.

Left column: all sites (unmedicated/medicated = 20/56).

Right column: JHU only (unmedicated/medicated = 4/43).

b) Larger regression coefficients between PANSS and MTLN connectivity in patients with affective psychosis compared to those with non-affective psychosis.

The upper/lower rows and left/right columns are the same as in Figure 4a. Affective/non-affective psychosis = 13/63 and 13/34 for all sites and JHU only, respectively.

c) Larger regression coefficient between PANSS and between-network connectivity of the MTLN in patients without (n = 41) than in those with (n = 6) comorbidity (JHU only).

Abbreviations

BGN-MbThal, midbrain and thalamus part of the basal ganglia network; Btw, between; FEP, first-episode psychosis; JHU, Johns Hopkins University; MTLN, medial temporal lobe network; PANSS, positive and negative syndrome scale; tSNR, temporal signal-to-noise ratio.
