15

16 **Abstract**

17 The Rhesus D antigen (RhD) has been associated with susceptibility to several viral infections.

18 Reports suggest that RhD-negative individuals are better protected against infectious

19 diseases and have overall better health. However, potential mechanisms contributing to

20 these associations have not yet been defined. Here, we used transcriptomic and genomic data

21 from the *Milieu Interieur* cohort of 1000 healthy individuals to explore the effect of RhD on

22 immune responses. We used the rs590787 SNP in the RHD gene to classify the 1000 donors

23 as either RhD-positive or -negative. Whole blood was stimulated with LPS, polyIC, and the live

24 influenza A virus and the NanoString human immunology panel of 560 genes used to assess

25 donor immune response and to investigate sex specific effects. Using regression analysis, we

26 observed no significant differences in responses to polyIC or LPS between RhD-positive and -

27 negative individuals. However, upon sex-specific analysis, we observed over 30 differentially

28 expressed genes (DEGs) between RhD-positive (n=401) and RhD-negative males (n=78).

29 Interestingly these Rhesus-associated differences were not seen in females. Further

30 investigation, using gene set enrichment analysis, revealed enhanced IFN γ signalling in RhD-

31 negative males. This amplified IFN γ signalling axis may explain the increased viral resistance
32 previously described in RhD-negative individuals.

33

34 **Introduction**

35 The Rhesus D blood group antigen (RhD) system is an important clinical factor in transfusion
36 and obstetric medicine. RhD status is determined based on the presence or absence of the
37 rhesus antigen, a transmembrane protein found on the surface of red blood cells (Avent and
38 Reid, 2000). The function of the RhD antigen is largely unknown, although it may play a role
39 in maintaining erythrocyte membrane integrity or transport of ammonium and carbon
40 dioxide (Marini *et al.*, 2000; Westhoff, 2004; Endeward *et al.*, 2008). The rhesus protein is
41 highly immunogenic and resulting antibodies can induce severe adverse reactions in RhD-
42 negative individuals should they encounter the D antigen following an unmatched blood
43 transfusion. RhD-negative women can also be sensitised during pregnancy with an RhD-
44 positive foetus or during delivery, often leading to haemolytic disease of the new born in
45 subsequent pregnancies with RhD-positive foetuses (Pegoraro *et al.*, 2020).

46

47 Although less well studied, RhD status is also known to influence several other health
48 outcomes (Dahlén *et al.*, 2021). An agnostic analysis of 1217 disease states found an
49 association between RhD status and hypertension during pregnancy (Dahlén *et al.*, 2021).
50 Several studies have demonstrated that RhD-positive and -negative subjects differ in
51 resistance to the pathological effects of aging, fatigue, and smoking (Flegr, Hoffmann and
52 Dammann, 2015). RhD-negative individuals also appear to be protected against infection,
53 including latent toxoplasmosis (Flegr, Hoffmann and Dammann, 2015). RhD status also
54 appears to affect susceptibility to SARS-CoV-2; in a study of 14,112 donors, RhD-negative
55 individuals had a lower risk of initial infection, intubation and death- suggesting a protective
56 role for RhD negativity (Zietz, Zucker and Tatonetti, 2020). RhD negativity varies substantially
57 across different populations and may potentially confer an as yet unknown fitness advantage
58 (Perry *et al.*, 2012). A major challenge in determining potential effects of RhD status on anti-
59 viral immunity is the lack of large, relevant human cohort studies with the power to detect
60 potentially subtle immune differences.

61

62 The *Milieu Interieur (MI)* study is comprised of a cohort of 1000 healthy individuals, stratified
63 by age (20-69, n=200 per decade) and sex (500 males and 500 females). The overall aim of
64 the MI study is greater understanding of the determinants of variation in the immune
65 responsiveness of healthy adult humans (Thomas *et al.*, 2015). Previous work from MI and
66 others has shown that sex and CMV serostatus are key drivers of variation in the human
67 immune response (Patin *et al.*, 2018; Picarda and Benedict, 2018). Substantial genomic and
68 transcriptomic data has been generated on the cohort to date and analysed using agnostic
69 approaches (Patin *et al.*, 2018, Piasecka *et al.*, 2018).

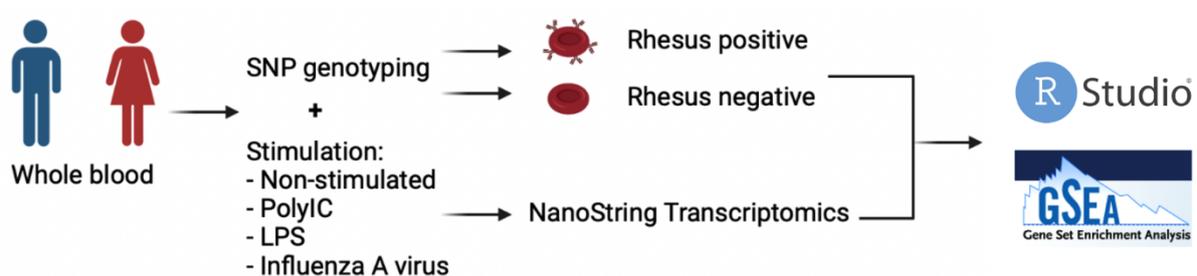

70

71 Here, we used genotype data on the rs590787 single nucleotide polymorphism (SNP) in RhD
72 to classify individuals from the MI study as either RhD-positive or -negative, an approach that
73 has previously been used to determine RhD status in several studies (Park, Cheong and Lee,
74 2014; Shi and Luo, 2019; Ali *et al.*, 2020). Individuals who are RhD-negative are homozygous
75 for the recessive alleles (CC), while RhD-positive individuals are heterozygous or
76 homonymous dominant (CT, TT). Genomic data was integrated with transcriptomic data from
77 whole blood stimulated with bacterial and viral ligands, LPS and polyIC, and the live influenza
78 A virus, to investigate whether Rhesus status was associated with induced immune responses.
79 We were particularly interested to compare RhD-positive and -negative males and females,
80 as sex is emerging as a key factor in determining outcomes to viral infection, especially SARS-
81 CoV-2 and influenza (Klein *et al.*, 2020).

82

83 Results

84

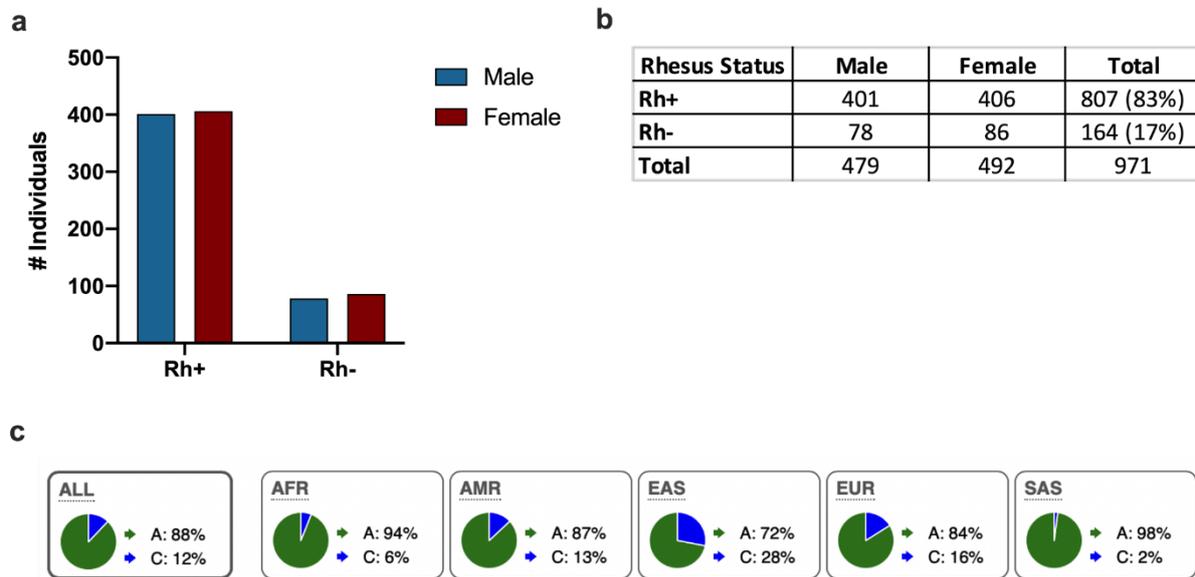

85

86 **Figure 1. Schematic overview of the study.** Genomic variability was assessed through a
87 genome wide SNP array. Rhesus status was determined based on the the rs590787 SNP. Whole
88 blood samples were stimulated with a panel of ligands (polyIC and LPS) and a live Influenza A

89 virus. The expression of 560 immune related genes was quantified using NanoString
 90 transcriptomics. R and gene set enrichment analysis (GSEA) were used to compare the
 91 response between RhD-positive and -negative individuals.

92

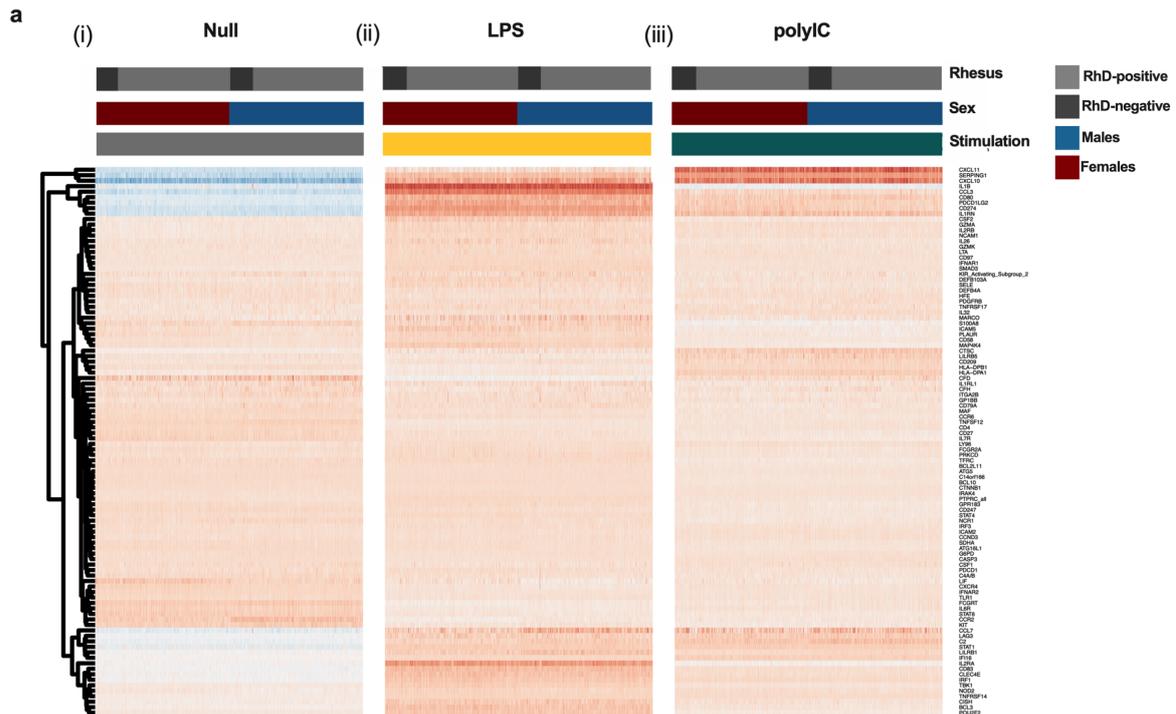

93

94 **Figure 2. Rhesus phenotype distribution of all individuals in the Milieu Interieur cohort.** RhD
 95 status was determined based on rs590787, a SNP in the RHD gene, using the Human Exome
 96 Bead Chip. **(a)** The frequencies of RhD-positive and -negative individuals was similar between
 97 males and females. **(b-c)** The genotype frequencies for the European cohort from the 1000
 98 Genome Project were similar to those recorded for the MI cohort. The numbers in brackets are
 99 percentages.

100

101 **Rhesus status distribution is similar between males and females.**

102 The presence or absence of rs590787, a SNP in the RhD gene, was used to determine the RhD
 103 status of donors in our cohort **(Fig.1)** (Shi and Luo, 2019). There was no difference in the
 104 distribution of RhD-positive or -negative individuals between males and females in our cohort
 105 **(Fig. 2a)**. 83% of donors in the MI cohort were RhD-positive **(Fig. 2b)**. The genotype
 106 frequencies of the Rhesus SNP rs590787 were compared to those from the 1000 genomes
 107 cohort (Auton *et al.*, 2015). The genotype frequencies in the MI cohort were similar to those
 108 observed for Europeans in the 1000 Genome Study **(Fig. 2c)**.

109

110 **Figure 3. Rhesus antigenicity does not affect immune gene expression at baseline or in**
 111 **response to stimulation with PRR ligands in whole blood.**

117

118 **Rhesus factor does not affect immune gene expression at baseline or in response to**
 119 **stimulation with PRR ligands in whole blood.**

120 Whole blood was incubated for 22 hours and expression of 560 immune genes quantified.
 121 Gene expression in the unstimulated condition was similar between all RhD-positive and -
 122 negative individuals. Given the important sex-specific differences emerging regarding
 123 pathogen susceptibility, we also investigated sex-specific effects. The cohort was also
 124 stratified by sex and assessed for differential gene expression between RhD-positive and -
 125 negative males and females. Baseline immune gene expression was similar between RhD-
 126 positive and -negative males and females (**Fig. 3(i)**).

127

144 *virus and gene expression assessed using NanoString. (a) Volcano plot showing no significant*
145 *differences between RhD-positive and -negative females ($q > 0.1$, regression analysis with FDR*
146 *adjustment). (b) Volcano plot of the differentially expressed genes between RhD-positive and*
147 *-negative donors in the male group ($q < 0.1$, regression analysis with FDR adjustment). (c)*
148 *Heatmap of DEGs from RhD-negative males. (d) Enrichment plot indicating upregulation of*
149 *the IFN γ pathway in the RhD-negative males ($p < 0.0001$).*

150

151 **Increased IFN γ mediated responses in RhD-negative males only.**

152 Infection with a live virus results in the activation of several PRRs and downstream pathways
153 that upregulate pro-inflammatory cytokines and antiviral mechanisms, and help clear
154 infection (Chen *et al.*, 2018). To determine whether the Rhesus factor has an impact on the
155 antiviral response to a live virus, we stimulated whole blood with the live influenza A virus.
156 No significant difference was observed between RhD-positive and -negative individuals when
157 comparing the entire cohort, or when looking at females only (**Fig. 4a**). Interestingly, however,
158 when examining the whole blood response to influenza A virus between RhD-positive and -
159 negative males only, we observed differential expression of 35 immune related genes (**Fig.**
160 **4b, Fig. 4c**; $q < 0.1$, regression analysis with FDR correction). To further interrogate differences
161 in the immune response to influenza A between RhD-positive and -negative individuals we
162 used gene set enrichment analysis (GSEA). Using this approach we found the IFN γ pathway to
163 be significantly enriched in RhD-negative males (**Fig. 4d**).

164

165 **Discussion**

166 In a French cohort of 1000 well characterised healthy individuals, we investigated the impact
167 of RhD on the innate immune response. Following stimulation with live Influenza A virus, we
168 found differential expression of 35 immune genes between RhD-positive and -negative males.
169 In contrast RhD-negative and positive women had similar responses to influenza A virus.
170 Further analysis of the differentially expressed genes revealed enrichment for IFN γ signalling
171 in RhD-negative males. The increased IFN γ signalling found here in RhD-negative males may
172 begin to explain their reduced susceptibility to infection.

173

174 Several association studies have found a relationship between RhD-negativity and enhanced
175 resistance to viral infection (Flegr, 2013; Flegr, Hoffmann and Dammann, 2015; Zietz, Zucker
176 and Tatonetti, 2020; Dahlén *et al.*, 2021). However, systemic analysis of immune activity by
177 RhD status had never been carried out. RhD-negative individuals have reduced risk of initial
178 infection with SARS-CoV-2, as well as decreased risk of both intubation and death (Zietz,
179 Zucker and Tatonetti, 2020). The increased IFN γ signalling that we find in RhD-negative donors
180 could contribute to reduced susceptibility to SARS-CoV-2 infection and pathology.

181

182 This study analysed transcriptomic data from studies using well described PRR ligands, LPS
183 and polyIC, which are mimics relevant to bacterial and viral infection. We also chose to include
184 a more complex live stimulus, the influenza A virus. The responses to the bacterial and viral
185 mimics in RhD-positive and -negative individuals were similar across all groups. Studies of cells
186 from other blood types including the Lewis (Le) group found no differences in expression in
187 responses to LPS between Le+ and Le- individuals in either males or females (Heneghan,
188 McCarthy and Moran, 2000). Another study found associations between the inheritance of
189 polymorphisms in genes that encode and regulate the expression of the Lewis blood antigens
190 and protection against infections with *Helicobacter pylori* (Björkholm *et al.*, 2001). This
191 suggests that analysis focused exclusively on specific TLR ligands may not be sufficient to
192 identify differential effects of blood groups on the innate immune response to infectious
193 agents. Studies using whole organisms may be more informative.

194

195 Here, using stimulation with the influenza A (but not the surrogate ligand polyIC) we observed
196 significant differential expression of 35 immune genes between RhD-positive and -negative
197 males. Influenza A viral pathogenesis has already been described as different between sexes,
198 with males at risk of developing more severe disease compared with females of a similar age
199 (Klein, Hodgson and Robinson, 2012). Recent studies have shown that females mount a more
200 robust immune response and have increased production of several key inflammatory proteins
201 known to be important in control of viral infection (Takahashi *et al.*, 2020). This more potent
202 innate immune response in females could mask potential differences in RhD-positive and -
203 negative females in our system.

204

205 The distribution of blood groups, including RhD, varies globally- this may explain, at least in
206 part, the regional differences in disease occurrence. RhD-negativity is particularly enriched in
207 East Asian populations (28% RhD-negative) compared with European or African populations
208 (16% and 6%, respectively) (Dahlén *et al.*, 2021). This may reflect the different historic disease
209 burdens on these populations. As the cohort used in our study includes only donors of
210 Western European descent, more cohorts should be analysed to include individuals of
211 difference ethnicities to further probe the differences in the immune response between RhD-
212 positive and -negative individuals.

213

214 While non-communicable disease states have been studied in the context of blood antigens,
215 viral illness is often overlooked as it is typically transient and often underreported (Roberts *et*
216 *al.*, 2019). Further association studies exploring the relationships between blood types and
217 viral infection are warranted to fully understand the contribution of blood type to risk of
218 severe viral disease. Findings from these studies may inform clinical management of patients
219 based on RhD status. Recently, Alsten *et al.* looked at differences in 96 circulating
220 inflammatory proteins between several blood groups. While RhD was not among those
221 examined, differences were found in the circulating inflammatory profiles of ABO and Duffy
222 blood types (Van Alsten *et al.*, 2021).

223

224 In this study we found evidence of an enhanced IFN γ mediated immune response in RhD-
225 negative males. IFN γ has been shown to be important in the control of several viral infections,
226 including Ebola and SARS-CoV-2 (Rhein *et al.*, 2015; Ruetsch *et al.*, 2021). The enhanced
227 signature observed in RhD-negative individuals in our cohort may contribute to the increased
228 resistance to infection described in these individuals. The enhanced gene signature was not
229 reflected at the protein level. However, this discrepancy could be explained by the relatively
230 low induction of IFN γ by influenza in our system, or by differences in the kinetics of IFN γ
231 protein and its downstream transcripts. Increased responsiveness to IFN γ by RhD-negative
232 individuals could also explain the enhanced IFN γ response in the absence of an increase in
233 IFN γ protein.

234

235 Although modest, the differences between RhD-positive and -negative males were
236 widespread and may contribute to the increased viral resistance reported elsewhere. Several
237 genes related to natural killer cells, including CD160 and KIRs, were among those that are
238 upregulated in RhD-negative individuals. NK cells, potent IFN γ producers and cytotoxic
239 lymphocytes, are key players in control of viral infection. While there was no difference in NK
240 cell counts in our cohort, the differences observed in marker expression could be indicative
241 of an increased activation state and IFN γ production (Vivier *et al.*, 2008). These findings are
242 the first to shed light on the potential immune differences between RhD-positive and -
243 negative individuals and support the use of systemic investigations to understand the impact
244 of blood types on the whole blood immune response.

245

246 **Materials and Methods**

247

248 **Study Population**

249 Healthy individuals were included in this study, equally distributed across sex (500 males and
250 500 females) and age (20-69, with 200 individuals per decade). Only individuals of western
251 European decent (i.e. French citizens for whom the last three generations of ancestors were
252 from mainland France) were included (Thomas *et al.*, 2015). The *Milieu Intérieur* Cohort,
253 which was approved by the Comité de Protection des Personnes – Ouest 6 (Committee for
254 the protection of persons) on June 13th, 2012 and by French Agence nationale de sécurité du
255 médicament (ANSM) on June 22nd, 2012. The study was sponsored by Institut Pasteur
256 (Pasteur ID-RCB Number: 2012-A00238-35) and was conducted as a single centre
257 interventional study without an investigational product. The original protocol was registered
258 under ClinicalTrials.gov (study# NCT01699893). The samples and data used in this study were
259 formally established as the *Milieu Interieur* biocollection (NCT03905993), with approvals by
260 the Comité de Protection des Personnes – Sud Méditerranée and the Commission nationale
261 de l'informatique et des libertés (CNIL) on April 11, 2018. The study was designed and
262 conducted in accordance with the Declaration of Helsinki and good clinical practice, with all
263 subjects giving informed consent.

264

265 **SNP genotyping and determining RhD status**

266 All participants were genotyped for the rs590787 SNP, through a genome-wide SNP array,
267 using HumanOmniExpress and HumanExomeBeadChips (Patin *et al.*, 2018). Rhesus status
268 (RhD-positive or -negative) was determined based upon the presence or absence of the
269 rs590787 polymorphism in the gene sequence of each individual (Shi and Luo, 2019).

270

271 **Whole blood stimulation**

272 Whole blood was taken from each participant and 1ml aliquoted into TruCulture tubes
273 preloaded with the chosen stimuli: polyIC (20µg/ml), LPS (10ng/ml) and influenza A virus
274 (H1N1 PR8; 100 HAU) as previously described (Duffy *et al.*, 2014) (**Fig. 1**). Tubes were
275 incubated on a bench top heat block for 22 hours. Supernatants were harvested for
276 proteomics. The cell pellet was resuspended in Trizol for later RNA extraction and
277 transcriptomics.

278

279 **NanoString transcriptomics**

280 Total RNA was extracted from the TruCulture cell pellets for the 1000 Milieu Interieur donors
281 using NucleoSpin 96 miRNA kit (Macherey-Nagel). RNA concentrations were measured using
282 Quantifluor RNA system kit (Promega) and RNA integrity numbers were determined using the
283 Agilent RNA 6000 Nano kit (Agilent Technologies). The expression levels of 560 immune
284 related genes were quantified before and after stimulation using NanoString hybridization
285 arrays, producing highly reproducible transcriptomic data. Gene expression data were
286 normalized as previously described (Piasecka, Duffy, Urrutia, Quach, Patin, Posseme,
287 Bergstedt, Charbit, Rouilly, Cameron R MacPherson, *et al.*, 2018).

288

289 **Statistical analysis**

290 Transcriptomic data was analysed using R Studio ([https://www.rstudio.com/.](https://www.rstudio.com/)) In order to
291 account for potential sex differences the cohort was subdivided into males and females.
292 Linear regression including CMV serostatus as a covariate was used to assess differences
293 between RhD-positive and -negative individuals. p-values were adjusted for false discovery
294 using the FDR correction to generate a q-value. A q-value of q<0.1 was taken as significant.
295 Scatterplots were created using GraphPad Prism. Volcano plots were created in R studio using
296 the EnhancedVolcano package. Heatmaps were generated in R using the package pheatmap.

297

298 **Pathway analysis**

299 Pathway analysis was carried out on genes with q-values (<0.1), using Gene Set Enrichment
300 Analysis, found at <https://www.gsea-msigdb.org/gsea/index.jsp>. The genes were compared
301 to panels of genes using the Hallmarks gene set.
