Abstract

Background: Transcriptomic studies usually focus on gene or exon-based annotations, and only limited experiments have reported the changes in the reads mapping to introns. The analysis of intronic reads allows the detection of nascent transcription that is not influenced by steady -state RNA levels and provides information on actively transcribed genes.

Methods: Here we describe substantial intronic transcriptional changes in Parkinson's Disease (PD) patients compared to healthy controls (CO) at two different timepoints, at the time of diagnosis (BL) and three years later (V08). We used blood RNA-seq data from the Parkinson's Progression Markers Initiative (PPMI) cohort subjects and identified significantly changed transcription of intronic reads only in PD patients during this follow up time.

Results: In CO subjects, only nine transcripts demonstrated differentially expressed introns between visits BL and V08. However, in PD patients 4,873 transcripts had differentially

expressed introns at visit V08 compared to BL, many of them with clear connection to

25   neurodegenerative diseases, such as *LRRK2, C9orf72, LGALS3, KANSL1AS1, ALS2*. In addition,

at the time of diagnosis (BL visit) we identified 836 transcripts (e.g. *SNCA, DNAJC19, PRRG4*)

and at visit V08 2,184 transcripts (e.g. *PINK1, GBA, ALS2, PLEKHM1*) with differential intronic

expression specific to PD patients. In contrast, reads mapping to exonic regions demonstrated

little variation indicating high specificity of changes in intronic transcription.

30   **Conclusion:** Our study shows that Parkinson's disease is characterized by substantial changes

in the nascent transcription and description of these changes could help to understand the

molecular pathology underpinning this disease.

35   transcript; nascent RNA; PPMI; blood transcriptome

Introduction

The analysis of the transcriptome is usually based on reads matching exons and gene-based annotations. A large proportion of the reads from RNA-sequencing map to the intronic

40   sequences and this is valid for both ribosomal depleted and poly-A selected RNA protocols [1]. It has been described that 38% of total RNA seq reads and only 8% of polyA RNA reads map to the introns [1]. The significance of the intronic reads has remained controversial and this part of the transcriptome is mostly neglected in transcriptomic analyses [2]. However, recent studies have shown that the reads mapping to introns are genuine and reflect the

45   immediate regulatory responses in transcription compared to post-transcriptional or steady-state changes [2, 3]. The intronic reads reflect the presence of the newly transcribed RNA and as such are useful to explore the complexity of the nascent RNA transcription and co-transcriptional splicing [4-6]. The analysis of intronic reads has been used to develop a detailed transcriptional model within a single sample showing the utility of intronic reads to

50   estimate the genome-wide pre-mRNA synthesis rate [7]. It's also been reported that intronic coverage was related to nascent transcription and co-transcriptional splicing [1]. The levels of intronic reads precede the change in exonic reads by 15 minutes, making them very useful to detect immediate responsive changes in the transcriptome [5]. Therefore, analysis of the intronic reads allows the separation of nascent transcription from post-transcriptional

55   changes during the formation of the genome-wide transcriptome.

Parkinson's Disease (PD) is one of the commonest neurodegenerative diseases with several clearly identified genetic mutations and variations associated with the disease [8-11]. The exact mechanisms of the disease are still not clear and given the complexity of the neuropathology of PD, the genomic network leading to the pathology are similarly likely to

60   be both complex and multifactorial [12-14]. Several studies have attempted transcriptomic

analysis correlating with PD and identified transcriptional signatures specific to the disease or involved in the regulation of the splicing of genes expressed in the basal ganglia [15, 16]. The analysis of peripheral tissue transcriptomes (blood and skin) overlaid on CNS PD data has identified significant differences between PD and control transcriptomic profiles [12, 17, 18].

65 These studies underlined the importance of peripheral tissue analysis to not only determine biomarkers correlating with the disease but also gain insight into neurodegenerative diseases. In this longitudinal study we compared the blood intronic transcriptome of PD patients and healthy controls (Table 1) at two different timepoints of disease progression, at diagnosis (baseline, BL) and after three years follow up (V08). To address the immediate changes in the

70 transcriptome reflected by the changes in nascent RNA we used only reads mapping to the intronic sequences. Intronic data were compared with the exonic reads to differentiate steady-state transcription from nascent transcription. We used blood whole transcriptome data from the Parkinson's Progression Markers Initiative (PPMI) cohort that contains data of PD and control (CO) subjects at these two different timepoints in the trajectory of PD.

Materials and Methods

Datasets

In this study we utilized the Parkinson's Progression Markers Initiative (PPMI) cohort data that were downloaded from www.ppmi-info.org/data (16 May 2021). The PPMI is a longitudinal

80 cohort of Parkinson's patients with the aims to describe the progression and biomarkers of Parkinson's disease. The dataset contains whole transcriptome data from the blood together with genetic and clinical data. For the RNA-seq 1µg of RNA isolated from PaxGene tubes was used and sequencing was performed at Hudson's Alpha's Genomic Services Lab on an Illumina NovaSeq6000. All samples under went rRNA and globin reduction, followed by directional

85 cDNA synthesis using the NEB kit. Following second-strand synthesis, library samples were prepared using the NEB/Kapa (NEBKAP) based library kit. Fastq files were merged and aligned to GRCh38p12 by STAR (v2.6.1d) on GENCODE v29.

Analytical Workflow

Bam files were imported to the R environment?ref/irl and intronic reads were called using

90 packages "GenomicFeatures" and "GenomicAlignments". Differential expression was detected using "DESeq2" and functionally annotated using "ReactomePA", "DOSE" and "clusterProfiler" packages.

Statistical analysis

Formal statistical analysis of differential expression of the intronic transcripts was performed

95 by using the "DESeq2" packages for R and only False Discovery Rate (FDR) corrected transcripts below 0.05 are reported. In addition, selection of FDR corrected transcripts was used for the pairwise comparison of the expression data and the plots were generated using "ggpubr" package.

Results

We analysed the intronic expression profiles in PD and CO subjects at the time of diagnosis (BL visit) and three years later (V08). There was little differential expression in exons in all our comparisons in both PD and CO groups, but there were many changes observed in intronic variation in the PD cohort which were highly significant and signify widespread active transcription in the blood from BL to V08. In addition, only few active transcription changes in the CO subjects were observed if we compared intronic transcripts at BL and V08 timepoints (Table 2). Remarkably, the differences in transcripts were identified almost exclusively only in introns and very few in exons (Table 2, Figure 1). More detailed description of our findings follows.

CO subjects

We analysed the longitudinal changes in the expression of the intronic reads of control subjects at BL and V08 timepoints and identified only limited differences. Nine transcripts showed differential intronic expression below FDR 0.05 (Supplementary Table 1). We also analysed the differential expression of the exonic transcripts, and nine transcripts were differentially expressed with exonic reads (Supplementary Table 2). This shows that on both intronic and exonic levels longitudinal differential expression in control subjects is quite limited and we can conclude that the transcriptome for control subjects is longitudinally very stable.

PD subjects

Next, we analysed only PD patients and compared their longitudinal intronic and exonic transcriptional profile. We identified 4,873 differentially expressed intronic reads in PD patients that differed between the time of diagnosis and after three years follow up (Supplementary Table 3). These 4,873 introns reflect the longitudinal change that is specific for PD patients during the three-year period. This is in stark contrast to the CO cohort that

exhibited a very stable transcriptome with very limited changes. At the same time, we detected only 8 exonic reads differentially expressed, showing the specificity of the intronic changes (Supplementary Table 4). Differentially expressed intronic reads were from several genes known to be involved in neurodegenerative diseases and PD, such as *LRRK2, VPS13C, LGALS3, C9orf72* and *ALS2* (Figure 2). We identified statistically significant upregulation of the intron 1 and intron 2 expression of the *PINK1* gene, showing that the intronic changes are not limited to single introns (Figure 3). *FLACC1, KANLS1AS1* and *CASP8AP2* were other genes in which differential intronic expression occurred (Figure 3). Taken together, we can conclude here that PD patients express overwhelming longitudinal changes in nascent transcription.

Baseline differences

We analysed PD versus CO at different timepoints to have two separate cross-sectional snapshots of transcriptional changes. At the time of diagnosis, PD patients had 836 introns differentially expressed compared to the controls (Supplementary Table 5). Only one exon was differentially expressed showing again that the enhanced intronic expression is a very specific feature of PD pathogenesis (Supplementary Table 6). Most remarkably, we identified *SNCA, GOLGA5* and *DNAJC19* genes with differentially expressed introns (Figure 4). *GOLGA5* is involved in the Golgi membrane and synaptic vesicle trafficking and docking [19]. *DNAJC19* or *TIMM14* is a chaperone that functions as an inner mitochondrial membrane co-chaperone and is responsible for mitochondrial protein import, a process that is involved in the pathogenesis of PD among others [20-22]. The gene *WDFY3* showed eight introns to be differentially upregulated in PD patients (Figure 5). This gene is responsible for mitochondrial quality control and is associated with multiple severe neurological pathologies as it is involved in brain energetics and mitophagy [23]. We also identified genes with differential intronic upregulation related to the immune response or to the age at onset of PD, such as *PLXNC1*,

150   *TNFAIP6* and *PRRG4* (Figure 6). These changes were found at the time of diagnosis and indicate already existing active transcriptional changes from the moment of clinical presentation of PD.

Differences at the three-year follow up visit (V08)

While it is important to have a cross sectional snapshot at the time of diagnosis, longitudinal

155   study design allow exploration of time-dependent alterations in the transcriptome. Three years after diagnosis, PD patients had 2,184 intronic transcripts differentially expressed (Supplementary Table 7). At the same time only 17 differentially-expressed transcripts were from exon sequences indicating again very high specificity toward intronic transcription (Supplementary Table 8). From all the detected 2,184 differential transcripts, 329 were

160   identical to the transcripts at the BL timepoint demonstrating major changes in nascent transcriptional changes in the PD group. Also, one transcript, *RP11-403I13.4-002*, was identical in the exonic and intronic analysis of V08 timepoint in the PD group. Figure 7 gives some details about the genes that have been identified to be involved in neurodegeneration. We identified longitudinal changes in the expression of *GBA-204* and *GBA-206* isoforms,

165   *LRRK2* and *PINK1*; genes that are well known to be involved in the pathogenesis of PD (Figure 7).

      Taken together, differential transcriptome analysis of introns and exons indicated specific and overwhelming changes in intronic transcription in PD patients compared to CO subjects, these differences were evident at the time of diagnosis and escalated during the

170   three-year progression of the disease.

Pathway analysis of longitudinal changes

We performed functional pathway analysis to identify the enriched pathways linked to the activated intronic transcription and to identify the common theme of these activated transcripts. As longitudinal PD changes were the most remarkable, we used only PD data for

175 pathway analysis and compared the intronic transcriptome profiles between the visits V08

and BL.

Although the analysis was performed in blood RNAseq, reactome enrichment analysis

identified that nervous system related themes were enriched in the differential profile of the

intronic transcription (Figure 8, Table 3). The pathways we identified were neuronal system,

180 protein-protein interactions at synapses, transmission across chemical synapses and muscle

contraction related pathways to name some (Table 2). Remarkably, activation of the neuronal

pathways was clear and is illustrated on Figure 8 as a bar plot and a dot plot showing the

number of genes identified and gene ratio. To illustrate this enrichment further, we used heat

and tree plots (Figure 9) showing again the large number of genes mapping to the pathways.

185 This indicated that the longitudinal changes in active transcription changes in the blood

maybe reflected changes in the nervous system and most likely reflected longitudinal

changes related to PD progression. This statement was further supported by the longitudinal

comparison of PD and CO groups separately. As very limited transcriptional alterations in the

longitudinal CO subgroup compared to PD subgroup were found, we can quite confidently

190 conclude that these pathways and biological functions are directly related to the progression

of PD.

KEGG enrichment analysis was performed to validate our previous pathway analysis

and to identify potential PD specific pathways (Figures 10 and 11). Indeed, when using KEGG

annotation, the most significantly changed pathways were ubiquitin mediated proteolysis,

195 protein processing in endoplasmic reticulum, mitophagy and autophagy. The activation of

protein processing in the endoplasmic reticulum (Figure 10) and the activation of mitophagy

pathway (Figure 11) during the time course of PD supports the causal relationship between

the transcripts and disease progression. All these pathways are directly involved in the pathogenesis of PD.

200   While we analyzed the blood whole transcriptome data, using the intronic reads helped to identify genes with active transcriptional change reflecting the dynamic alterations in the transcriptional balance of the cells. By using blood data on clinical samples, we were able to identify PD specific pathogenetic networks that have been identified to be involved in PD using cellular models and biochemical experiments. These results show that blood
205   transcriptome can reflect nascent transcription specific for the disease condition.

      Taken together, analysis of the intronic reads in the whole genome transcriptome study allows to detect active nascent transcription and gives much more detailed information compared to the exon centric steady-state analysis of transcription. We were able to show large scale intronic activation that helped to detect actively transcribed transcripts that we
210   were able to map into functionally and clinically relevant genetic networks. Intronic transcriptome analysis provides information about the condition-specific transcripts that can help to identify genomic patterns specific for the condition being studied.

Discussion

215 Whole transcriptome analysis is typically based on gene- or exon-based annotation, quite seldom transcript-based annotation is used [24, 25]. Gene-based annotation is an amalgamated approach where the reads mapping to different exons and transcripts will be merged under a single functional identifier, the gene [26]. This approach is the most widely used and therefore most of the whole transcriptome studies provide this aggregated

220 information. Inevitably, this approach leads to the loss of power to detect precise and detailed changes in transcription leading to the loss of the sensitivity of the tool. The avoidance of transcript-based annotation is understandable as the bioinformatics tools to call transcripts accurately from short read data are limited. Only recently Kallisto and Salmon were developed to provide quasi-mapping approach and accurate transcript calling to overcome

225 the issue with transcript detection [27, 28]. Nevertheless, using these tools nascent cannot be distinguished from steady state transcription.

Recently intronic mapping was suggested to be an alternative to identify the transcripts that were recently transcribed [2]. This approach, based on the co-transcriptional splicing and detection of introns, indicates that the transcripts still have introns included.

230 Detecting this event in the transcriptional process gives important additional power to measure the genes that are actively and newly transcribed compared to the steady state stable transcription in the background. The analysis of intronic transcripts has successfully been applied to human basal ganglia data with clear evidence for the reproducibility of the intronic eQTLs (i-eQTLs) and their utility to analyze the rate of transcription [15]. Interestingly,

235 in this paper the authors also identified highly specific enrichment of disease-specific transcription suggesting the suitability of the intron based transcriptional analysis. The

authors also confirmed the mapping of intronic signals to novel transcripts and validated a/the annotation-independent approach in transcriptomic analysis.

We have identified the longitudinal changes in intronic transcription in PD patients. The PD changes could be specific for the disease condition as only minor differences were found in the analysis of the controls. Indeed, functional annotation of the intronic transcripts revealed activation of pathways closely related to the pathophysiology of PD although only blood RNAseq was analyzed. The functional significance of that data awaits further analysis using patient derived cell lines, but the identified differences are intriguing as in many cases they reflected changes in the pathways related to neurodegenerative processes.

Out of many different transcripts identified in the present study, the ones with clear evidence for the mitochondrial function and proteostasis support the relevance of our findings in the context of the pathophysiology and progression of PD. The gene DNAJC19 or TIMM14 encodes for an inner mitochondrial membrane translocase that imports proteins to mitochondria and is directly involved in the pathogenesis of neurodegenerative diseases [20-22]. Products of TIMM genes interact with translocases of the outer mitochondrial membrane (TOMM) to form a transport pathway for the nuclearly encoded precursor proteins [20]. In our earlier study we identified TOMM20 to be involved in the neurodegeneration caused by the downregulation of WFS1 gene leading to mitochondrial damage [29]. In addition, in the present study we identified eight introns of the WDFY3 gene to be differentially upregulated in PD patients. WDFY3 functions as a conductor for aggregate clearance by autophagy and colocalises with the aggregated proteins [30]. WDFY3 is associated with multiple severe neurological pathologies by regulating brain bioenergetics, autophagy and mitophagy [23, 31-33]. The findings from single transcripts and intronic changes were further confirmed by functional annotation of differential expression and identification of the activation of

autophagy and mitophagy in PD patients. Changes in intronic transcription were evident at the time of diagnosis indicating concomitant transcriptional changes with the clinical presentation of the PD.

Comparison of the intronic and exonic signals has recently been systemically analyzed and the reflection of the nascent transcription by the intronic reads confirmed [2]. Several experimental studies indicate that intronic transcription is a reliable proxy to measure nascent transcription [7]. Moreover, comparing exonic reads to intronic signals helps to differentiate transcriptional changes from post-transcriptional changes. Therefore, the differences we have identified are caused by changes in active transcription and are not due to changes related to the normal physiological processes.

Conclusions

In conclusion, we identified highly specific longitudinal nascent transcriptional profile in the blood of Parkinson patients that possibly reflects the changes caused by the molecular pathological processes of the disease and are relevant to improve our understanding about the progression of the disease.

Legends to the figures

340   **Figure 1.** The figure illustrates the number of exonic and intronic reads in different subgroups and at different timepoints. The number of intronic reads is very high in PD patients compared to CO subjects. Exonic reads didn't change by the disease status or by the progression of the disease. It is also evident that the number of intronic reads increases from the baseline visit to three-year follow up.

345   **Figure 2.** Longitudinal differential expression of the intronic transcripts in PD patients, baseline (BL) compared to the V08 visit three years later. Panels A, B, C, D, E, F reflect changes in the introns for different transcripts. LRRK2, ALS2 and VPS13C are downregulated during the progression of PD. C9orf72, LGALS3 and LGALSL are upregulated within three years of PD.

     Figure 3. Longitudinal differential expression of the intronic transcripts in PD patients, BL

350   compared to the V08 visit. The panels A, B, E, F, G, H reflect changes in the introns for different transcripts. Panels C and D illustrate changes for PINK1-201 transcripts, introns 1 and 2.

     Figure 4. Cross-sectional analysis of the intronic transcripts at the baseline visit (BL), at the time of enrolment of the subjects. PD patients had decreased expression of the SNCA-216, DNAJC19-211 and MRPS10-201 transcripts. The transcripts GOLGA5-201, CPQ-201 and UBR5-

355   208 were upregulated.

     Figure 5. Cross-sectional analysis of the intronic transcripts at the baseline visit (BL), at the time of enrolment of the subjects. PD patients had increase expression of 8 introns of the WDFY3 gene.

     Figure 6. Cross-sectional analysis of the intronic transcripts at the baseline visit (BL), at the

360   time of enrolment of the subjects. Different introns of the transcripts related to the immune response were up regulated in PD patients.

     Figure 7. Cross-sectional analysis of the intronic transcripts at the V08 visit, three years after enrolment of the subjects. Two different transcripts of GBA, LRRK2-203, ARHGAP27-204 and PLEKHM1-212 were upregulated in PD patients. Intorns1 and 2 of the PINK1-201 transcript

365   were also upregulated. ALS2-251 transcript was downregulated in PD patients.

     Figure 8. Reactome pathway analysis indicates longitudinal enrichment of the neuronal themes in the blood transcriptome of the PD patients. **(a)** Bar plot of all statistically significant

enriched pathways indicates the different number of genes for each pathway. (**b**) Dot plot of the enriched pathways shows the relation between the gene count, gene ratio and adjusted p-values.

Figure 9. Reactome pathway analysis identified several neuronal pathways enriched longitudinally in PD blood transcriptome. (**a**) Heat plot showing individual genes and their mapping to pathways; (**b**) Tree plot illustrates clustering of the pathways, number of matched genes and adjusted p-values.

Figure 10. KEGG pathway of the protein processing in the endoplasmic reticulum and the mapped genes from the intronic transcriptome. Mapped genes are in red, green, or grey colors.

Figure 11. KEGG mitophagy pathway. Longitudinal blood intronic transcriptome profile of Parkinson disease mapped significantly to the mitophagy pathway. Mapped genes are in red, green, or grey colours.

Figure 1. The figure illustrates the number of exonic and intronic reads in different subgroups and at different timepoints

Figure 2. Longitudinal differential expression of the intronic transcripts in PD patients, baseline (BL) compared to the V08 visit three years later. Panels A, B, C, D, E, F reflect changes in the introns for different transcripts. LRRK2, ALS2 and VPS13C are downregulated during the progression of PD. C9orf72, LGALS3 and LGALSL are upregulated within three years of PD.

Figure 3. Longitudinal differential expression of the intronic transcripts in PD patients, BL compared to the V08 visit. The panels A, B, E, F, G, H reflect changes in the introns for different transcripts. Panels C and D illustrate changes for PINK1-201 transcripts, introns 1 and 2.

Figure 4. Cross-sectional analysis of the intronic transcripts at the baseline visit (BL), at the time of enrolment of the subjects. PD patients had decreased expression of the SNCA-216, DNAJC19-211 and MRPS10-201 transcripts. The transcripts GOLGA5-201, CPQ-201 and UBR5-208 were
555 upregulated.

Figure 5. Cross-sectional analysis of the intronic transcripts at the baseline visit (BL), at the time of enrolment of the subjects. PD patients had increase expression of 8 introns of the WDFY3 gene.

Figure 6. Cross-sectional analysis of the intronic transcripts at the baseline visit (BL), at the time of enrolment of the subjects. Different introns of the transcripts related to the immune response were up regulated in PD patients.

Figure 7. Cross-sectional analysis of the intronic transcripts at the V08 visit, three years after enrolment of the subjects. Two different transcripts of GBA, LRRK2-203, ARHGAP27-204 and PLEKHM1-212 were upregulated in PD patients. Intorns1 and 2 of the PINK1-201 transcript were also upregulated. ALS2-251 transcript was downregulated in PD patients.

(**a**)　　　　　　　　　　　　　　　　　(**b**)

Figure 8. Reactome pathway analysis indicates longitudinal enrichment of the neuronal themes in the blood transcriptome of the PD patients. (**a**) Barplot of all statistically significant enriched pathways indicates the different number of genes for each pathway. (**b**) Dotplot of the enriched pathways shows the relation between the gene count, gene ratio and adjusted p-values. Key appears cut off on my screen

Figure 9. Reactome pathway analysis identified several neuronal pathways enriched longitudinally in PD blood transcriptome. (**a**) Heat plot showing individual genes and their mapping to pathways; (**b**) Tree plot illustrates clustering of the pathways, number of matched genes and adjusted p-values.

Figure 10. KEGG pathway of protein processing in the endoplasmic reticulum and the mapped genes from the intronic transcriptome. Mapped genes are in red, green, or grey colours. Indicate what colours correspond to – up /down/ unchanged

Figure 11. KEGG mitophagy pathway. Longitudinal blood intronic transcriptome profile of Parkinson disease mapped significantly to the mitophagy pathway. Mapped genes are in red, green, or grey colours.
