Cover title:
POST-STROKE EXECUTIVE FUNCTION

ABSTRACT

BACKGROUND

There is a high prevalence of executive function impairments among stroke survivors. However, the underlying aetiology remains unclear. In particular, we address whether focal, stroke-specific white matter damage or diffuse comorbid white matter damage (leukoaraiosis) is more associated with executive function impairments.

METHODS

This project is a retrospective analysis of data collected within the Oxford Cognitive Screening programme. Patients were recruited in the acute stage of stroke if they had a confirmed diagnosis of stroke, were at least 18 years of age, were able to remain alert for 20 minutes, and were able to provide informed consent. Patients in the present analysis completed follow up neuropsychological assessment at six-months with the Oxford Cognitive Screen-Plus to assess executive function. Stroke lesions were manually delineated on acute clinical brain scans allowing us to quantify focal stroke-specific white matter damage using the HCP-842 tractography atlas. Leukoaraiosis was visually rated on clinical scans using the Age-Related White Matter Changes scale.

RESULTS

This study included data from 90 stroke patients (mean age = 73.76 years; 47.78% female). Multiple linear regression analyses showed that the presence of leukoaraiosis predicted poorer executive functioning six-months after stroke (B = -0.33, p = .031, 95% CI [-0.64 - 0.03]). However, post-stroke executive functioning was not predicted by stroke-specific damage to white matter tracts.

CONCLUSIONS

Overall, these results provide novel insight into the neural substrates underlying post-stroke executive dysfunction and highlight the prognostic utility of using routine clinical CT scans to assess leukoaraiosis.

INTRODUCTION

Stroke is the third most important cause of disability burden worldwide.[1,2] Whilst stroke mortality rates have decreased due to improved acute care,[3] there is a higher prevalence of chronic stroke survivors.[4] Prevalence of post-stroke cognitive impairment is high[5] with in particular executive dysfunction estimated to affect between 19% and 75% of chronic stroke survivors.[6,7,8] Post-stroke executive function impairment has been associated with reduced quality of life,[9] disability in activities of daily living,[10] and increased mortality.[11]

Post-stroke executive dysfunction has been linked to focal lesions affecting white matter pathways[12] as well as diffuse leukoaraiosis,[13,14] which affects 64-86% of stroke patients.[15,16] However, previous studies have investigated the role of stroke-specific white matter damage or leukoaraiosis in isolation and have not studied how these conditions might interact in the same sample. Furthermore, the published studies yield comparatively ungeneralisable results due to their reliance on MRI, which is not suitable for a significant, non-random portion of the stroke population (e.g., patients with implants).[17]

This investigation aims to clarify the relative contributions of stroke-specific white matter damage and leukoaraiosis to post-stroke executive dysfunction using routine clinical CT brain scans from a representative sample of chronic stroke survivors.

METHODS

Standard Protocol Approvals, Registrations, and Patient Consents

This project represents a retrospective analysis of data collected within the Oxford Cognitive Screening (OCS) programme,[18] which recruited stroke survivors during acute hospitalisation and conducted follow up neuropsychological assessments at six-months. The OCS

programme received NHS ethics approval (OCS-Tablet and OCS-Recovery studies, NHS RECs 14/LO/0648 and 18/SC/0550). All patients provided written or witnessed informed consent at recruitment and at follow up.

Participants

The OCS programme recruited a consecutive sample of stroke survivors and included all patients who had a confirmed diagnosis of acute stroke, were at least 18 years of age, were able to remain alert for 20 minutes, and were able to provide informed consent.

Patients were considered for inclusion in this investigation if they had completed the follow up assessment with the more detailed Oxford Cognitive Screen-Plus (OCS-Plus)[19] executive function assessment at six-months after stroke ($n = 185$). Patients were excluded where no usable scan was available ($n = 59$); scan showed evidence of additional or different pathology ($n = 3$); OCS-Plus assessment was incomplete ($n = 13$); or multiple strokes were visible on scan ($n = 20$). Although patients with multiple, temporally distinct strokes could have been included in the leukoaraiosis analysis, the inclusion of these patients would complicate the interpretation of the focal white matter damage analyses. Therefore, these patients were excluded from both analyses so that cohorts were comparable, to facilitate informative comparisons of the relative contributions of focal lesions and leukoaraiosis to executive dysfunction. Demographic details of the resultant sample of 90 stroke survivors as reported by relevant medical records are presented in Table 1.

[Insert Table 1]

Cognitive data

Executive function was assessed using the OCS-Plus, a tablet-based cognitive screen designed to provide fine-grained measures of memory and executive function.[19] This tool has been validated versus standardised pen-and-paper neuropsychological assessments in a large, normative aging sample.[19] The OCS-Plus is specifically designed to tap executive function subdomains with minimal interference from impairments within separate cognitive domains (e.g., language, memory).[20] In total, the OCS-Plus takes approximately 25 minutes to complete.[19] In the present investigation, data from the OCS-Plus Trails, Rule Finding, and Selection tasks were considered.

First, the OCS-Plus Trails Task measures set-switching and is a variation of standard pen-and-paper Trail Making Test.[21] This task requires patients to connect a series of shapes according to specific rules (Supplementary Figure 1-1). In the final subtest, patients are required to connect both circles and squares in alternating order, connecting circles in decreasing order of size and squares in increasing order of size. Performance was evaluated by summing the number of correct connections made on this rule-switching condition (range = 0-14).

The OCS-Plus Rule Finding Task measures complex executive attention and is analogous to the Brixton Spatial Anticipation test,[22] but can be administered more quickly and places lower demands on working memory. Patients are shown three columns of squares and triangles which regularly vary in luminosity (Supplementary Figure 1-2). A red dot is placed within a shape, then moves throughout the array according to a specific but changing spatial rule. Patients are instructed to learn the rule guiding the dot's movement and predict

where the dot will appear next. Performance was scored based on the number of correct location predictions made (range = 0-46).

Finally, the OCS-Plus Selection Task measures strategic search as well as working memory. Patients are allowed three minutes to identify and select all line drawings of fruits in a search matrix (Supplementary Figure 1-3). Patients are instructed to select each target stimulus once, whilst ignoring irrelevant distractors. Importantly, no visible record of previous responses is provided therefore making this analogous to "invisible cancellation" and loading spatial working memory as patients are required to keep track of previously found items.[23] Performance was scored by summing the number of targets successfully identified (range = 0-30).

To attain an overall measure of executive functioning, individual performance on each of these three OCS-Plus task scores were z-score transformed using the data collected in this study, and the average z-score was used to quantify overall executive functioning ability for each patient. This approach has the advantage that it encapsulates the unity and diversity of executive functioning subdomains (i.e., updating, inhibition, and shifting),[24] in contrast to previous studies that considered performance on a single executive function test.[12]

Lesion analyses

Acute whole-brain CT data (slice thickness 5 mm) were collected for each patient (range = 0-13 days post-stroke). Stroke lesions were manually delineated on native space scans by two trained and blinded researchers (GH and MM) using the MRIcron software package (McCausland Center for Brain Imaging, Columbia, SC, USA). The resultant lesion masks were smoothed at 5 mm full width at half maximum in the z-direction and binarised using a

threshold of 0.5. Scans and lesion masks were reoriented to the anterior commissure and warped into 1 x 1 x 1 mm stereotaxic space using the Statistical Parametric Mapping 12 and Clinical Toolbox.[25] Normalised scans and lesion masks were visually inspected for quality. These binarised lesion masks were used to calculate stroke volume and white matter disconnection severity statistics.

Stroke-specific white matter damage was quantified in terms of white matter tract disconnection severities, which were estimated using a lesion quantification toolkit.[26] This toolkit estimates tract-level disconnection for 70 canonical white matter tracts, as defined by the HCP-842 streamline tractography atlas,[27] with the corpus callosum divided into five segments based on Freesurfer corpus callosum segmentation. The toolkit works by embedding the lesion into the HCP-842 as a region of interest (ROI) and iteratively loading the streamline trajectories for each of the tracts. The files are filtered to retain only those streamlines that intersect the volume occupied by the lesion. For each tract, the percentage disconnection severity is calculated by converting the number of disconnected streamlines into a percentage of the total number of streamlines assigned to that tract. Given that anatomical homologues of some white matter ROIs exist within both hemispheres, this investigation calculated separate metrics for each of these homologues, then averaged across hemispheres to produce a single measure per patient for each ROI.

For statistical analysis, ROI disconnection was binarised as present (at least 10% disconnection) or absent (less than 10% disconnection) for each ROI.[26] The number of disconnected ROIs was then summed to create an overall measure of stroke-related white matter disconnection for each patient.

White matter ratings

Leukoaraiosis as visualised on the clinical CT scans was evaluated using the Age-Related White Matter Changes visual rating scale (ARWMC scale).[28] Visual ratings were assigned by a trained rater (GH), who was blinded to behavioural results. Leukoaraiosis was assessed in five regions within each hemisphere (10 regions total): frontal, parieto-occipital, temporal, infratentorial, and basal ganglia. Each region was assigned a score of 0-3 according to the criteria in Supplementary Table 1. In cases where a brain region was severely affected by stroke damage so that leukoaraiosis could not be evaluated, the affected region was assigned the same score as the anatomically homologous region in the opposite hemisphere. A total score reflecting the severity of leukoaraiosis across the entire brain was calculated by summing the assigned scores across all ten regions (range = 0-30). This total score was used to categorise leukoaraiosis as absent (0), mild (1-5), moderate (6-10), or severe (>10).[29]

Statistical analysis

Behavioural and clinical data were cleaned before analysis. Mean substitution was employed to impute missing values for patient age ($n = 8$), education ($n = 39$), and lesion volume ($n = 4$). For all multiple linear regression analyses, residual plots were visually inspected to test the assumptions of linearity, normality of residuals, and homogeneity of residuals variance. Where appropriate, a 5% false discovery rate correction was applied to correct for inflated false positive rates due to multiple comparisons. All regression analyses included age, sex, years of education, stroke type (ischaemic, haemorrhagic), stroke lateralisation (left, right, bilateral), stroke territory (anterior cerebral artery, middle cerebral artery, posterior cerebral artery, vertebrobasilar, intraventricular, multiple territories) and stroke volume as covariates of no interest.

First, a multiple linear regression analysis was conducted to investigate whether post-stroke executive function is predicted by white matter tract disconnection severity due to focal stroke damage. In this analysis, the overall white matter disconnection score (number of ROIs with at least 10% disconnection) was included as a predictor variable. Next, a multiple linear regression was conducted to investigate whether post-stroke executive function is predicted by the presence of leukoaraiosis. Finally, we planned to conduct a multiple linear regression to investigate whether post-stroke executive function is better predicted by the presence of leukoaraiosis or by overall stroke-specific white matter tract disconnection severity. Full statistics for each conducted analysis are reported in Supplementary Materials. Overall, these analyses aimed to clarify whether post-stroke executive function is predicted by focal stroke-specific white matter damage and/or leukoaraiosis.

Data Availability

All data used in the analyses of the present study have been made openly available on the Open Science Framework (https://osf.io/r4h3m/).

RESULTS

First, basic descriptive analyses were conducted to investigate data from the behavioural, lesion, and leukoaraiosis measures employed in this study. The mean scores for the OCS-Plus Trails, Rule Finding, and Selection tasks were 8.20 (SD = 4.35, range = 0-14), 18.26 (SD = 8.30, range = 2-37), and 25.49 (SD = 5.28, range = 3-30), respectively. Figure 1 shows the distribution of scores for these tasks, relative to the mean scores derived from normative data.[19]

[Insert Figure 1]

Lesion anatomy was available for 86 patients because of four further exclusions for this analysis due to poor spatial normalisation of the lesion masks. Figure 2 presents a lesion overlay for these patients, demonstrating good coverage for this investigation's target ROIs. Table 2 shows the descriptive statistics for each included ROI, and also demonstrates a good level of lesion coverage across ROIs considered in the present investigation (Table 2). According to the overall stroke-specific white matter disconnection score, the average number of ROIs disconnected by at least 10% was 10.17 (SD = 8.70, range = 0-34).

[Insert Figure 2 here]

[Insert Table 2 here]

Leukoaraiosis was categorised as absent, mild, moderate, or severe in 32, 35, 15, and 8 patients, respectively. Leukoaraiosis was also binarised as simply present (n = 58) or absent (n = 32) for some of the subsequent statistical analyses.

Next, the relationship between stroke-specific white matter ROI disconnection and executive function was analysed using the overall white matter disconnection score (number of ROIs disconnected by at least 10%). The executive function score was not significantly predicted by the overall stroke-specific white matter disconnection measure (B = 0.00, p = .784, 95% CI [-0.02 0.03]), although age was a significant negative predictor of executive function at p < .001. To verify that this null result was not a consequence of quantifying white matter disconnection across multiple white matter tracts, further multiple linear regressions were conducted with individual ROI disconnections included as continuous

predictor variables and binarised predictor variables. Even before correction for multiple comparisons, these analyses confirmed that executive function was not significantly predicted by stroke-specific disconnection of any individual white matter ROIs (see Supplementary Table 2).

Next, a linear regression was conducted to investigate the relationship between executive function score and the presence of leukoaraiosis. This model was found to be significant ($F(13, 76) = 4.24$, $p < .001$, $R^2 = .42$, $R^2_{Adjusted} = .32$.), with post-stroke executive function being significantly poorer in patients with leukoaraiosis, compared to patients without leukoaraiosis ($B = -0.33$, $p = .032$, 95% CI [-0.63 -0.03]). (Figure 3). Additionally, patient age ($B = -0.03$, $p < .001$, 95% CI [-0.04 -0.02]) and the occurrence of a single stroke impacting multiple vascular territories versus a single vascular territory (anterior cerebral artery) ($B = -1.03$, $p = .027$, 95% CI [-1.95, -0.12]) were found to be significant predictors of lower executive function scores. No other covariates were found to be significant.

DISCUSSION

The purpose of this study was to investigate the association between post-stroke executive functioning and both focal stroke-specific white matter damage and leukoaraiosis in a clinically representative sample of chronic stroke survivors. The presence of leukoaraiosis was found to be a significant predictor of reduced executive function scores, while stroke-specific white matter damage was not. These findings provide novel insight into the neural substrates underlying post-stroke executive function impairments and demonstrate the prognostic utility of leukoaraiosis measures as reported by routinely collected CT scans.

First, stroke-specific damage to white matter ROIs was not a significant predictor of executive functioning. This finding differs from previous studies that have linked executive function to specific white matter tracts.[30,31,32] In a voxel-lesion symptom mapping study, researchers identified an association between executive functioning and damage to both the superior longitudinal fasciculus and anterior corona in a sample of traumatic brain injury patients.[33] However, the analysis did not control for lesion volume and only considered data from relatively young patients who would be less likely to exhibit age-related reductions in white matter integrity (leukoaraiosis) that may impair executive functioning. Previous stroke lesion-mapping studies have linked damage to the left superior longitudinal fasciculus with deficits on the Trail Making Tests.[12] However, we note that traditional lesion-mapping approaches may not represent a valid methodology for investigating the correlates of diffuse, disconnection syndromes because lesion-mapping analyses tend to "average" locations of involved anatomy rather than accurately localising spatially distinct but equally critical structures. The present investigation avoided this issue by quantifying stroke-specific white matter damage using a ROI-based approach instead.

While stroke-specific white matter damage was not significantly associated with executive function after stroke, the presence of leukoaraiosis as reported by routinely collected CT scans was. This finding is critically important as it suggests that post-stroke executive dysfunction may not always be caused by patterns of localised stroke-specific damage, but instead may be linked to large-scale network integrity issues caused by white matter degeneration. The present investigation adds to previous studies[13,14] by demonstrating that leukoaraiosis is not only a key predictor of executive dysfunction, but that it may act as a more informative measure than stroke-specific white matter damage.

The findings of this study are also important to consider in the context of current methodological practices. Leukoaraiosis detected on CT is generally thought to represent an underestimation of white matter pathology.[34,35] Although CT may indeed underestimate the spatial extent and severity of changes in white matter integrity, this investigation demonstrates that CT detects levels of leukoaraiosis that correlate meaningfully with post-stroke cognitive outcome. CT-based measures should therefore be considered for use in research studies of white matter disease to ensure generalisability of findings to real-world populations, since restriction to MRI will result in substantial selection bias. Previous cohort studies have demonstrated that CT and MRI data can be harmonized to produce comparable ratings where one or other imaging modality has been used according to feasibility and tolerability.[29,5] In addition, since CT is the most commonly used imaging method for routine clinical assessment of stroke, it is important to understand its prognostic value. Such data from CT-brain imaging could be incorporated into clinical risk prediction algorithms, particularly should automated assessment methods become available.

Several potential limitations are present within this study. First, any research aiming to link neuroanatomy to behavioural impairments must make a number of methodological choices that may ultimately bias results.[36] For example, in this study, executive dysfunction was quantified by averaging performance across three standardised metrics. This approach aimed to provide a comprehensive assessment of executive function subdomains[24] but independent assessment of subdomains may have generated different results. Similarly, leukoaraiosis was quantified using the ARWMC scale but alternative rating scales are available (e.g., Fazekas scale[37]), so future studies should assess whether our results can be replicated using other rating scales.

Furthermore, this investigation combined acute imaging data with chronic behavioural data, which is not ideal because brain networks undergo substantial reorganisation and regeneration during stroke recovery due to neural plasticity.[38] This cortical reorganisation may weaken statistical brain-behaviour relationships as patients who exhibited executive dysfunction at the acute stage may have recovered by the time of chronic assessment. Future investigations are needed to determine whether the results on the lack of relationship between executive function and the stroke-specific white matter damage found here generalise to patients in the acute stage post-stroke.

Overall, this investigation provides important insight into the neurological basis of post-stroke executive dysfunction. Specifically, the present study found that leukoaraiosis was associated with poorer executive functioning among a clinically representative sample of chronic stroke survivors, even though stroke-specific white matter damage was not. This observation demonstrates that pre-existing white matter pathology may well impact post-stroke cognitive outcomes to a greater extent than any stroke-specific white matter damage.

FIGURES AND TABLES

Table 1. A breakdown of patient demographic and clinical information.

Demographics	Statistics
Years of age, mean (*S.D.*)	73.76 (11.72)
Years of education, mean (*S.D.*)	12.74 (3.67)
Scan date (days), mean (*S.D.*)	1.04 (2.42)
Stroke volume (cm^3), mean (*S.D.*)	45.97 (114.75)
Sex, N	
Female	43
Male	47
Stroke type, N	
Ischaemic	64
Haemorrhagic	26
Stroke lateralisation, N	
Unilateral left hemisphere	42
Unilateral right hemisphere	45
Bilateral*	3
Stroke location, N	
Anterior cerebral artery (ACA)	3
Middle cerebral artery (MCA)	64
Posterior cerebral artery (PCA)	8
Vertebrobasilar	7
Intraventricular	3
Multiple territories	5

Bilateral stroke was defined as a single stroke crossing the midline.
S.D. = standard deviation.

Figure 1. Distribution of scores for the OCS-Plus Trails, Rule Finding, and Selection tasks acquired in the present study. Data from the present study (histograms) are plotted against the mean scores obtained from a normative aging sample (dotted lines).

Figure 2. A lesion overlay map of the study sample (n = 86), with colour indicating the number of patients with lesions in each area. MNI coordinates of each transverse section (z-axis) are provided.

Table 2. Descriptive statistics for each ROI from the HCP-842.

ROI	*n*	*n ≥ 10%*	*Mean (% disconnection)*	*S.D.*
Anterior commissure	42	31	24.97	37.92
Arcuate fasciculus	48	38	18.30	21.93
Acoustic radiation	37	31	14.62	20.73
Cerebellum	15	7	2.41	7.38
Corpus callosum (anterior)	33	12	5.24	12.25
Corpus callosum (mid-anterior)	45	24	11.80	23.62
Corpus callosum (central)	31	23	15.16	30.04
Corpus callosum (mid-posterior)	44	20	15.47	31.31
Corpus callosum (posterior)	61	28	20.92	32.90
Corticospinal tract	59	42	20.13	22.32
Corticostriatal tract	72	33	10.87	12.71
Central tegmental tract	10	9	5.94	19.52
Corticothalamic pathway	75	38	13.31	16.00
Cingulum	31	16	5.81	12.82
Dorsal longitudinal fasciculus	9	9	6.88	22.18
Extreme capsule	46	40	20.20	22.37
Frontal aslant tract	32	28	9.64	15.68
Frontopontine tract	53	40	18.20	20.96
Fornix	16	15	8.65	22.40
Inferior cerebellar penducle	10	10	4.82	14.61
Inferior fronto-occipital fasciculus	49	37	17.80	22.81
Inferior longitudinal fasciculus	34	22	9.82	18.22
Lateral lemniscus	6	6	3.01	11.29
Middle cerebellar peduncle	12	8	3.33	10.77
Medial longitudinal fasciculus	6	5	4.57	18.87
Medial lemniscus	21	19	9.27	17.87
Middle longitudinal fasciculus	33	28	15.20	22.16
Occipitopontine tract	40	33	16.98	22.37
Optic radiation	32	25	12.80	21.59
Posterior commissure	14	7	7.25	25.57
Parietopontine tract	53	36	18.02	21.45
Reticulospinal tract	7	7	3.22	12.32
Superior cerebellar peduncle	29	16	9.82	20.76
Superior longitudinal fasciculus	38	25	10.35	16.51
Spinothalamic tract	24	22	9.29	17.38
Temporopontine tract	35	31	15.81	22.04
Uncinate fasciculus	24	14	7.36	16.04
U-fibers	61	21	7.54	10.25
Vermis	10	9	8.24	25.77
Vertical occipital fasciculus	14	10	4.52	12.70

n = number of patients with any ROI disconnection. n ≥ 10% = number of patients with at least 10% ROI disconnection. S.D. = standard deviation.

Figure 3. Relationship between leukoaraiosis and the composite executive function score. The means and standard deviations are plotted (in black) along with individual patient scores (points).
