Abstract

Objective We studied the association between the coronavirus disease 2019 (COVID-19) pandemic, including the restrictive measures, and metabolic risk factors for cardiovascular disease (CVD) in women and men. Next, we analysed whether changes in these metabolic risk factors were mediated by psychological and behavioural mechanisms.

Design In this natural experiment, we assessed changes from baseline in metabolic CVD risk factors in the exposed group (whose follow-up measurements were taken during the pandemic), and compared these to the changes in the control group (whose follow-up measurements were taken before the pandemic).

Participants This study used data from 6962 participants from six different ethnic groups (Dutch, South-Asian Surinamese, African Surinamese, Ghanaian, Turkish and Moroccan) of the HELIUS study, based in Amsterdam, the Netherlands. We included women and men without prior CVD, who participated in both the baseline (2011-2015) and follow-up measurements (2019-2021).

Outcome measures Changes between baseline and follow-up measurements in six metabolic CVD risk factors were calculated for systolic and diastolic blood pressure (SBP, DBP), total cholesterol (TC), fasting plasma glucose (FPG), haemoglobin A1c (HbA1c), and estimated glomerular filtration rate (eGFR).

Results The exposed group experienced somewhat less favourable changes over time in SBP, DBP and FPG (the latter only in women) than the control group, while temporal changes in HbA1c and eGFR were more favourable among the control group. For instance, SBP was 1.119 mmHg [0.046, 2.193] higher in exposed than non-exposed women, and 1.380 [0.288, 2471] in men. Changes in SBP and DBP were partially mediated by changes in behavioural factors, most notably BMI and alcohol consumption.

Conclusions The COVID-19 pandemic, including the restrictive lockdown measures, is associated with a deterioration of several CVD risk factors in women and men. These findings may aid in decision making concerning the management of and the recovery following the pandemic.

Article Summary

Strengths and limitations of this study

- The COVID19 pandemic lockdown measures led to a pause in the data collection for the prospective, population-based HELIUS study, which shaped a natural experiment.

- Natural experiments, as quasi-experimental designs, are generally considered stronger than cross-sectional studies.

- Through inverse-probability weighting, this study aimed to account for baseline differences between the control and exposed group.

- We could not adjust for differences in follow-up time that occurred as a result of the restrictive measures, which may have affected estimates of variables that change with age.

- The effects of certain mediators may be underestimated, as the data available for defining these variables were largely based on self-reports.

Funding The HELIUS study is funded by the Dutch Heart Foundation (grant 2010T084), the Netherlands Organization for Health Research and Development (ZonMw; grant 200500003), the European Union (FP-7; grant 278901), and the European Fund for the Integration of non-EU immigrants (EIF; grant 2013EIF013). This work was additionally supported by ZonMw Gender and Health Program (grant 849200008).

Conflict of interests None declared

Introduction

Cardiovascular disease (CVD) is a major cause of morbidity and mortality worldwide [1], and the coronavirus disease 2019 (COVID-19) pandemic is speculated to cause a surge in CVD [2]. Globally, the COVID-19 pandemic has disrupted life for most people, with lockdowns, social distancing and other measures implemented to reduce the spread of the virus. In addition to the direct effect of the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) on CVD [3], the restrictive measures might have led to changes in behavioural and psychosocial factors that could negatively affect metabolic CVD risk factors. Understanding how the current pandemic affects cardiometabolic health could lead to better prevention and monitoring of high-risk groups, and may aid decision making surrounding the management of the current and future virus outbreaks.

The impact of pandemics on metabolic CVD risk factors has not been examined. However, major disruptions of the social or physical environment, e.g., after natural disasters, may affect cardiometabolic health. Natural disasters have been linked to deteriorations in metabolic CVD risk factors such as hypertension (HT), Diabetes Mellitus type 2 (DM) and hypercholesterolemia [4-9].

Besides sex differences in COVID-19, the restrictive measures are known to affect women and men differently socially, behaviourally, and psychologically, for example concerning women's and men's work, caregiving, psychological distress and health behaviour, such as diets and exercise [10-18]. These differences might translate into sex differences in the effect of the pandemic on metabolic CVD risk factors. Findings on sex differences in response to natural disasters are mixed, with some studies reporting no differences [4], better [5] or worse [7] health outcomes for women than men. Whether these results can be extrapolated to sex differences in the effect of the current pandemic on metabolic CVD risk factors is yet to be empirically determined.

We carried out a natural experiment on the effect of the pandemic on temporal change in six metabolic CVD risk factors [19]: systolic and diastolic blood pressure (SBP, DBP), total cholesterol (TC), fasting plasma glucose (FPG), Haemoglobin A1c (HbA1c), and

estimated glomerular filtration rate (eGFR). We determined whether the effect of the pandemic on metabolic CVD risk factors differed between women and men aged 18-70 without prior CVD. Second, we explored to what extent observed differences were mediated by depressive symptoms, negative life events (NLEs) and health behaviour.

Methods

HELIUS

Our study is nested within the population-based Healthy Life in an Urban Setting (HELIUS) study, a multi-ethnic cohort study in Amsterdam, the Netherlands [20]. Baseline data were collected between 2011 and 2015 among 24,789 Dutch, South-Asian Surinamese, African Surinamese, Ghanaian, Moroccan, and Turkish origin women and men aged 18-70 years living in Amsterdam. Potential participants were sampled with a simple random sampling method from the municipality registry, after stratification by ethnicity as defined by registered country of birth [21]. The second wave of data collection among participants started in May 2019 and is currently ongoing. Data were obtained by questionnaire and physical examinations (including biological samples).

Research Ethics Approval

The HELIUS study has been approved by the AMC Ethical Review Board. All participants provided written informed consent.

Study design

We performed a natural experiment, comparing participants exposed to the pandemic and the restrictive measures during follow-up measurements to those not exposed. This was possible because follow-up data collection was done partially before and partially after the first lockdown (Figure 1). We can thus distinguish between a control group that was examined between the start of data collection on 15 May 2019 until the pause of data collection on 14 March 2020, when the Netherlands entered into its first lockdown [10], and

an exposed group whose data were collected when data collection was resumed after the first lockdown ended on 7 July 2020, and 30 December 2020. The exposed group was examined in a period with increasing infections and corresponding restrictive measures. For a more detailed description of the Dutch lockdown measures, please refer to Yerkes et al., 2020 [10].

People who participated in both the baseline and follow-up measurement were included (N=8,324). First, those with unknown (N=21), Javanese (N=99) or other Surinamese ethnicity (N=118) were excluded because separate analyses in these groups were not possible due to low power. Next, those with prior CVD (N=1035) or missing data on CVD (n=89) were excluded. The final sample consisted of 6962 participants, 5100 in the control group and 1862 in the exposed group. Cases with missing values were excluded from analyses.

Metabolic CVD risk factors

We calculated changes from baseline in traditional metabolic CVD risk factors available for both waves, specifically SBP, DBP, HbA1c, FPG, TC, and eGFR [19], by subtracting baseline values from follow-up measurements. Data collection protocols and methods were similar at both time points: SBP and DBP were measured in duplicate on the participants' left arm using an automated digital blood pressure (BP) device after the participant had been sitting for five minutes. To determine FPG, HbA1c, TC and serum creatinine, fasting blood samples were drawn after an overnight fast. FPG was determined in plasma samples by using enzymatic spectrophotometric UV method, using hexokinase as primary enzyme (Roche Diagnostics), and HbA1c was determined in whole blood samples through HPLC technology (Tosoh). Serum creatinine was determined using a kinetic colorimetric spectrophotometric isotope dilution mass spectrometry-calibrated method (Roche Diagnostics), and eGFR was calculated using the CKDEPI (CKD epidemiology collaboration) creatinine equation [22].

Covariates

Socio-demographic data were assessed by questionnaire. Ethnicity was defined by the participant's and their parents' country of birth [21]: a person was defined as belonging to one of the included minority groups if (1) he/she was born outside the Netherlands with at least one parent born outside the Netherlands (first generation) or (2) he/she was born in the Netherlands but both parents were born outside the Netherlands (second generation). For the Dutch sample, people born in the Netherlands whose parents were also born in the Netherlands, were invited. Surinamese participants were further classified according to self-reported ethnic origin into 'African', 'South-Asian' or 'other'. We used highest attained educational level, labour market participation and occupational level as a proxies for socioeconomic status (SES). Educational level was categorized into three categories: lower (no education, elementary education or lower vocational or lower secondary education), intermediate (intermediate vocational or intermediate or higher secondary education), or high (higher vocational education or university). Labour market participation consisted of four categories: employed, not in employment (including retirees, students, homemakers), unemployed and/or social benefit recipients, and occupationally disabled. Occupational level was classified according to the Dutch Standard Occupational Classification system, which provides an extensive systematic list of all professions in the Dutch system. Occupational level consisted of five categories, based on job title and job description [23], and consisted of five levels: elementary, lower, intermediate, higher, and scientific occupations.

Mediators

Changes in depressive symptoms was calculated by subtracting baseline from follow-up values. Depressive symptoms were assessed via the Patient Health Questionnaire (PHQ-9), a validated instrument [24] measuring depressive mood in the past two weeks. Change in BMI was calculated by subtracting baseline BMI from follow-up BMI, with weight measured in light clothing and height measured without shoes [20]. Self-reported smoking status, alcohol use and NLE were assessed via questionnaire. Smoking status measured whether people

are current smokers, have never smoked or have previously smoked, which was recoded into those who quit or started smoking between baseline and follow-up, and no change. Alcohol use consisted of the categories low, intermediate and high, which was recoded into decreased, equal or increased alcohol use between baseline and follow-up. NLEs at follow-up assessed whether people reported recently experiencing a NLE, such as illness, death of a loved one or other adverse experiences, recoded into yes or no.

Data analysis

Socio-demographic variables and mediators were presented as means [standard deviations (SD)], or frequencies [percentages], by control or exposed group and sex.

We performed linear regression analyses, stratified by sex, with change in metabolic risk factors as dependent variables, and exposure to the lockdown as the main predictor. Possible selection bias and the effect of phasing of the HELIUS data collection (i.e., for organizational reasons different neighbourhoods in Amsterdam were invited sequentially) could lead to baseline differences between the control and exposed group due to social and ethnic characteristics of neighbourhoods. To account for these differences, we used inverse probability weighting (IPW) on baseline values of the metabolic CVD risk factors and sociodemographic factors [25]. This means weights are created for the likelihood of being exposed to the pandemic based on baseline factors, to balance the control and exposed group.

Because of the effect of the pandemic on behavioural and psychosocial factors, we explored the mediating effect of behavioural and psychosocial factors on the association between exposure to the pandemic and change in metabolic risk factors for which a difference between the control and exposed group was found. Specifically, we described change in smoking status, alcohol use, BMI and depressive symptoms, and the presence of recent NLEs [2,16,17,26], and compared the model without mediators to the model with all mediators to measure whether these psychological and behavioural mechanisms contributed to the observed differences between the control and exposed group. Next, we added the

mediators separately to see which factors contributed most to these changes. Decreases of ≥10% in the beta's were considered to be indicative of a mediation effect. For eGFR, we additionally explored to what extent changes in SBP and DBP explained observed differences.

As medication use or seasonal effects might affect comparisons, we repeated the main analyses, first, after excluding participants who were receiving HT and/or DM medication at baseline and, second, after excluding participants measured between January and June from the control group to ensure comparisons across similar time periods [27].

Additionally, we verified if differences were present across educational levels (as a proxy of socioeconomic status; SES) and ethnic groups, given that the pandemic may differently affect various groups within society [10,11,14,28].

Finally, we conducted a supplemental analysis to explore to what degree observed effects varied across time. We distinguished between two time periods in the exposed group: the 'early post-lockdown period' between data collection resumption until 21 September 2020, representing a period with limited measures and a low infection rate after the first wave subsided, and 21 September until 30 December 2020, the 'late post-lockdown period', with implementation of new measures and increasing infection rates (the second wave [28]).

The analyses were conducted in R studio 4.0.3, with statistical significance determined at p-values <.05.

Results

Sample characteristics

56.2% of participants was female, the mean age was 45.8 (SD=12.5) at baseline and 52.0 (SD=12.6) at follow-up, with an average follow-up time of 6 years and 2 months (Table 1). The exposed group was significantly younger, more often higher educated and more often of Dutch origin than the control group. All baseline CVD risk factors, except TC, were more favourable among the exposed group.

Differences control and exposed group

We found small, yet statistically significant differences in crude mean change in metabolic CVD risk factors between the control and exposed group in women and men (Supplemental Table 1). SBP, DBP, and FPG increased more, and eGFR decreased less, in the exposed group than the control group. Change in TC was similar between groups, whereas changes in HbA1c decreased more in the exposed group.

In analyses weighted on baseline characteristics, these differences remained (Table 2, Figure 2). In the exposed group, women appeared to have slightly greater deteriorations in DBP and FPG, and smaller improvements in HbA1c compared to men, while men appeared to experience larger deteriorations in SBP and slightly smaller improvements in eGFR. These sex differences, however, were not statistically significant.

Mediation

We found significant differences in several potential mediators between the control and exposed group, such as a larger increase in BMI in the exposed group than the control group (Supplemental Table 6). Addition of these mediators partially explained observed differences in several risk factors between the control and exposed group. For instance, in the model with all mediators, the beta's of exposure to the pandemic on DBP decreased with 50.8% for women and 90% for men (Table 3). Changes in BMI and alcohol use, and smoking status for women, were associated with the largest changes in beta's for SBP, DBP and FPG (in men), but not HbA1c. Change in alcohol use, but not other mediators, nor SBP and DBP, partially mediated the relationship between exposure to the pandemic and change in eGFR (-11.8% among men compared -35.3% among women).

Supplemental analyses

Analyses excluding participants receiving HT and/or DM treatment and the analyses for seasonal effects did not change our interpretation of these findings (Supplemental Tables 2-3). Moreover, analyses stratified by SES and ethnicity, except for African Surinamese women

and Turkish men, confirmed the association between the pandemic on SBP, DBP and FPG, but not other measures (Supplemental Tables 4-5). However, groups were too small and confidence intervals too wide to assess whether differences within and between women and men varied by SES or ethnicity.

Finally, the analysis of time periods revealed that in both women and men, the associations between exposure to the pandemic and SBP, DBP, FPG and TC (in men), were larger in the late post-lockdown period compared to the early post-lockdown period (Supplemental Table 7).

Discussion

Women and men in the exposed group experienced slightly higher increases in SBP, DBP and FPG than the control group. Change in TC did not differ between groups, while the exposed group experienced slightly more favourable changes in HbA1c and eGFR relative to the control group. Patterns of differences did not vary significantly between women and men, and were observed across most ethnic and SES groups. Particularly in men, but also in women, changes in SBP, DBP, FPG and eGFR may have been partially mediated by behavioural factors, most notably changes in BMI and alcohol use. Psychosocial factors did not contribute substantially.

While natural experiments are generally considered strong [29], some limitations persist. First, response bias may have occurred [20] affecting generalizability to the general population. Moreover, random assignment to the control or exposed group was not possible, resulting in baseline differences between these groups. This may be due to phasing of the study, or selective drop-out among exposed participants. For instance, if only healthy participants were comfortable with being examined during the pandemic, this would result in a healthy subset of participants. We attempted to account for these differences through IPW, yet, this method does not account for potentially relevant unmeasured confounders. Despite this limitation, we chose IPW as our method to adjust for baseline differences and possible

selective drop-out as it uses the entire sample, whereas propensity score matching would have led to a loss of cases, thereby negatively affecting our power [25].

Moreover, we could not adjust for differences in follow-up time, as this is a direct result of the restrictive measures. Yet, this may have affected variables that change with age, e.g. eGFR and SBP. On average, SBP increases with 7 mmHg every ten years [30] and eGFR decreases with 1 mL/min/year rate [31]. Given that the difference in follow-up time between the control and exposed group is only several months, this is thus unlikely to completely explain our findings.

Furthermore, the effect of the mediators may have been underestimated, as measures characterizing change in behaviour may have been suboptimal, for example, only change in smoking status was available instead of amount and products smoked. Moreover, while we used the most common method of assessing these variables [20], some mediators were self-report data, which may be less accurate compared to other measurement methods [32].

Despite these limitations, we found significant differences in several metabolic CVD risk factors between the control and exposed group, suggesting a potential effect of the pandemic on future CVD risk in both women and men. The magnitude of the associations appears modest, since an average increase of e.g. 1.38 mmHg in SBP may not drastically alter an individual's CVD risk [33]. Yet, observed effects could potentially be problematic at the population level. Indeed, associations were found across SES- and ethnic subgroups, and density plots of several risk factors control or exposed group revealed that the difference reflects a slight shift in the entire distribution of risk factors (data not shown). Thus, in line with Rose's prevention paradox, this could imply a need for intervention strategies aimed at the total population rather than exclusively high-risk individuals [34].

In particular, our findings suggest the pandemic negatively affected BP and glycaemia. Elevated BP due to the pandemic is in line with prior research on social disruption following natural disasters [4,6-8]. Moreover, in line with prior research [8], we found evidence that the pandemic led to increased glycaemia, in particular FPG among women.

Findings concerning HbA1c seem contradictory, as the exposed group had slightly more favourable changes in HbA1c than the control group, despite the less favourable changes in FPG. This could be due to the inclusion of people with DM in our study, as studies have described better DM self-management during the lockdown due to improved medication compliance and adherence to dietary recommendations [15]. However, analyses excluding people receiving DM treatment show this is unlikely to explain these findings. Alternatively, HbA1c as a long-term measure of glycaemia may be less accurate in capturing the acute effects of the pandemic [35], which is supported by our finding that HbA1c values are worse in the late post-lockdown period.

We found no unfavourable association between exposure to the pandemic and other risk factors. Previous studies reported increased cholesterol following large disruptive events [5,6,9]. We found no effect on TC, despite the larger increase in BMI in the exposed group, which is evidently associated with TC [36]. We speculate this may be due to the specific underlying dietary- and lifestyle patterns in our population, which may associate more strongly with other measures of cholesterol than TC, such as HDL, LDL or triglycerides [36]. Moreover, contrary to our expectations, the exposed group experienced a smaller decline in eGFR than the control group. This decline was not likely due to hyperfiltration, as changes in SBP and DBP did not mediate the association between exposure to the pandemic and change in eGFR. Neither was this likely due to COVID-19 infections, as the association between the SARS-CoV-2 virus and acute kidney injury is small [37], and because the association was not larger in the ethnic group with the highest infection rate, Ghanaians [28], which would be expected if this effect was caused by COVID-19 infections. A more feasible explanation seems an overestimation of the eGFR, as creatinine levels at follow-up may have been influenced by changes in muscle mass, for instance due to decreased exercise during the lockdown [38].

The association between exposure to the pandemic and BP and glycaemia seem to be partially mediated by behavioural factors, in particular BMI and alcohol use, two well-known CVD risk factors. These observed differences are in line with studies on health

behaviour during the pandemic [12,13,15-17] and changes reported following natural disasters [6,39]. Strategies to promote healthy diets and exercise, reduce alcohol use and smoking could potentially be used in the recovery following the pandemic [40]. While several studies reported increased mental distress as a result of the pandemic [11,18], we found no effect of recent NLEs or change in depressive symptoms. However, given the continuation of the pandemic and the restrictive measures, long term implications of mental distress due to the pandemic are to be evaluated in prospective research. The mediating effects of other social and behavioural factors not assessed in this study, warrant further inquiry.

We found no evidence supporting sex differences in the effects of the pandemic, despite a body of literature reporting sex differences in changes in health behaviour due to the pandemic. Studies have reported unhealthier diets [14] and more psychological problems [11,18] among women, and worse sleeping patterns, decreased exercise [12], higher alcohol consumption [16] and higher risk of DM [13] among men during the pandemic. Thus, while the pandemic may have affected women and men differently socially, behaviourally and psychologically, this might not have translated into sex differences in the effect of the pandemic on CVD risk factors in the short term. Future research should determine whether this trend continues over the duration of the pandemic.

We conclude that the pandemic may have caused a modest deterioration of metabolic CVD risk factors in both women and men across ethnic and socioeconomic groups. These effects seem to be partially mediated by changes in health behaviour, possibly as a result of the restrictive measures during the pandemic. These results suggest a need to prepare for, and mitigate, potential long-term effects, and may be valuable in decision making surrounding the management of – and recovering following – the COVID-19 pandemic.

Declarations

Acknowledgments: The HELIUS study is conducted by the Amsterdam University Medical Centre, location AMC and the Public Health Service of Amsterdam. Both organizations provided core support for HELIUS. We are most grateful to the participants of the HELIUS study and the management team, research nurses, interviewers, research assistants and other staff who have taken part in gathering the data of this study. We also want to thank Dr. Ehsan Motazedi for critically reviewing our methodology.

Authors Contributions Contributors BH and IGMvV contributed to the conception and design of the work. BH drafted the manuscript. IGMvV, MAY, REH, HG, AEK, and AL critically revised the manuscript. All authors gave final approval and agree to be accountable for all aspects of work ensuring integrity and accuracy. The corresponding author attests that all listed authors meet authorship criteria and that no others meeting the criteria have been omitted. All gave final approval and agree to be accountable for all aspects of work ensuring integrity and accuracy.

TABLES

Table 1. Sociodemographic characteristics by sex and quasi-experimental group*

	Women		Men	
	Control	Exposed	Control	Exposed
Mean follow-up time in months [SD]	73.1 [13.8]	79.0 [12.4]	72.5 [13.4]	77.7 [12.3]
Mean age at baseline [SD]	46.3 [12.3]	44.0 [12.6]	46.4 [12.5]	44.6 [13.0]
Ethnicity				
Dutch	734 [25.7]	379 [36.1]	673 [30.0]	351 [43.2]
South-Asian Surinamese	520 [18.2]	120 [11.4]	360 [16.1]	81 [10.0]
African Surinamese	722 [25.2]	155 [14.8]	417 [18.6]	107 [13.2]
Ghanaian	243 [8.5]	113 [10.8]	189 [8.4]	73 [9.0]
Turkish	231 [8.1]	129 [12.3]	236 [10.5]	102 [12.6]
Moroccan	410 [14.3]	154 [14.7]	365 [16.3]	98 [12.1]
Education				
Lower	1114 [39.2]	337 [32.3]	792 [35.6]	215 [26.6]
Intermediate	837 [29.4]	264 [25.3]	645 [29]	224 [27.7]
High	894 [31.4]	441 [42.3]	787 [35.4]	370 [45.7]
Employment status				
Employed	1827 [64.4]	696 [66.9]	1682 [75.5]	621 [76.9]
Not in employment	538 [19.0]	175 [16.8]	207 [9.3]	78 [9.7]
Unemployed/Social benefit recipient	335 [11.8]	114 [11.0]	237 [10.6]	81 [10.0]
Occupationally disabled	137 [4.8]	55 [5.3]	102 [4.6]	28 [3.5]
Occupational level[1]				
Elementary	323 [13.2]	112 [12.5]	215 [10.4]	58 [7.7]
Lower	554 [22.7]	166 [18.5]	636 [30.8]	176 [23.5]
Intermediate	734 [30.1]	257 [28.6]	501 [24.2]	179 [23.9]
Higher	636 [26.1]	243 [27.0]	492 [23.8]	203 [27.1]
Scientific	192 [7.9]	121 [13.5]	224 [10.8]	133 [17.8]

[1] Missing on occupational level include both missing and not applicable, e.g., for people who have never worked (e.g., students, those occupationally disabled).

*With the exception of follow-up time and age, data are presented as frequencies [percentages].

Table 2. Linear regressions on the association between exposure to the pandemic, including lockdown measures, and temporal change in metabolic risk factors, by sex*

	Women		Men		Interaction	
	B [95% CI]	p-value	B [95% CI]	p-value	B [95% CI]	p-value
ΔSBP	1.119 [0.046, 2.193]	.041	1.380 [0.288, 2.471]	.013	-0.699 [-2.249, 0.851]	.377
ΔDBP	0.848 [0.232, 1.463]	.007	0.797 [0.107, 1.488]	.024	-0.044 [-0.969, 0.882]	.927
ΔTC	-0.054 [-0.117, 0.009]	.091	-0.005 [-0.074, 0.064]	.886	-0.052 [-0.146, 0.042]	.276
ΔFPG	0.121 [0.056, 0.185]	.000	0.022 [-0.066, 0.109]	.626	0.073 [-0.036, 0.181]	.189
ΔHbA1c	-0.645 [-0.974, -0.316]	.000	-0.835 [-1.370, -0.300]	.002	0.115 [-0.493, 0.722]	.712
ΔeGFR	1.062 [0.387, 1.737]	.002	1.041 [0.322, 1.760]	.005	-0.023 [-1.008, 0.961]	.963

*SBP, systolic blood pressure; DBP, diastolic blood pressure; TC, total cholesterol; FPG, fasting plasma glucose; HbA1c, haemoglobin A1c; eGFR, estimated glomerular filtration rate; CI, confidence intervals. The analyses were weighted on baseline measurements, age at baseline, educational level, ethnicity, occupational level and labour market participation. The interaction column tests the interaction between exposure to the pandemic and lockdown and sex.

Table 3. Linear regression on the association between exposure to the pandemic, including lockdown measures, and temporal change in metabolic risk factors, adjusting for mediators*

	Women			Men		
	B [95% CI]	p-value	%Δ in B	B [95% CI]	p-value	%Δ in B
