20
21 Running Title: Saliva Versus MTS for COVID-19 Detection

22
23 Key Points:

- 24
- 25 • Saliva is more sensitive in detecting symptomatic cases of COVID-19 than MTS early in
the course of infection.
 - 26 • Saliva performs best in the pre-symptomatic period.
 - 27 • Saliva and MTS demonstrated high agreement making saliva a suitable and cost-effective
28 COVID-19 screening tool.

29 Abstract

30

31 **Background:** Saliva is an attractive sample for detecting SARS-CoV-2 because it is easy to
32 collect and minimally invasive. However, contradictory reports exist concerning the sensitivity
33 of saliva versus nasal swabs.

34

35 **Methods:** We recruited and followed close contacts of COVID-19 cases for up to 14 days from
36 their last exposure and collected self-reported symptoms, mid-turbinate swabs (MTS) and saliva
37 every two or three days. Ct values and frequency of viral detection by MTS and saliva were
38 compared. Logistic regression was used to estimate the probability of detection by days since
39 symptom onset for the two sample types.

40

41 **Results:** We enrolled 58 contacts who provided a total of 200 saliva and MTS sample pairs; 14
42 contacts (13 with symptoms) had one or more positive samples. Overall, saliva and MTS had
43 similar rates of viral detection ($p=0.78$). Although Ct values for saliva were significantly greater
44 than for MTS ($p=0.014$), Cohen's Kappa demonstrated substantial agreement ($\kappa=0.83$).
45 However, sensitivity varied significantly with time relative to symptom onset. Early in the course
46 of infection (days -3 to 2), saliva had 12 times (95%CI: 1.2, 130) greater likelihood of detecting
47 viral RNA compared to MTS. After day 2, there was a non-significant trend to greater sensitivity
48 using MTS samples.

49

50 **Conclusion:** Saliva and MTS specimens demonstrated high agreement, making saliva a suitable
51 alternative to MTS nasal swabs for COVID-19 detection. Furthermore, saliva was more sensitive
52 than MTS early in the course of infection, suggesting that it may be a superior and cost-effective
53 screening tool for COVID-19.

54

55 Introduction

56 The U.S. Centers for Disease Control and Prevention (CDC) recommend the use of upper
57 respiratory specimens, including but not limited to nasopharyngeal, mid-turbinate nasal, anterior
58 nasal and saliva specimens for the initial diagnosis of COVID-19 [1]. Although nasopharyngeal
59 swabs (NPS) are considered to be the standard for the detection of COVID-19 by most
60 researchers, collection requires the use of trained professionals, can cause discomfort to the
61 patients, and may pose greater risks to healthcare workers during sample collection [1–4]. Mid-
62 turbinate swabs (MTS) are sometimes used as an alternative to NPS in an effort to reduce patient
63 discomfort and occupational exposures to healthcare workers [4–6]. Compared to swab-based
64 collection, saliva is even less invasive, more affordable, and can be self-collected with minimal
65 or no supervision [1,7,8].

66
67 Existing studies focusing on the sensitivity of NPS compared to MTS, and NPS compared to
68 saliva have produced contradictory results [2,4,9–11]. Few studies directly compare saliva and
69 MTS specimens. Previous studies demonstrated that pre-symptomatic transmission results in
70 higher secondary attack rates for both symptomatic and asymptomatic transmission [12,13].
71 However, most of the existing studies only looked at detection of symptomatic cases after
72 symptom onset [2,4,9,10] and few looked at detection sensitivity starting with the pre-
73 symptomatic period. Therefore, a study that conducts a direct comparison of MTS and saliva,
74 including an assessment of sensitivity over time (starting during the pre-symptomatic period) is
75 critical to identifying optimally sensitive methods for early detection and effective control of
76 SARS-CoV-2 transmission.

77
78 The purpose of this study was to compare the sensitivity of MTS and saliva specimens for
79 detecting SARS-CoV-2 by actively following close contacts of COVID-19 cases and collecting
80 MTS and saliva samples for real-time reverse transcription polymerase chain reaction (RT-PCR)
81 during their post-exposure quarantine period.

83 Methods

84 *Study population*

85 We analyzed MTS and saliva sample data from individuals who reported close contact with
86 confirmed COVID-19 cases as part of the University of Maryland StopCOVID study [14] from
87 May 2020 to April 2021.

89 *Questionnaire and sample collection*

90 Participants were followed every two or three days for up to 14 days from their last exposure or
91 until SARS-CoV-2 was detected in their samples. If one or more of their screening samples
92 became positive, results were confirmed by an appropriate clinical diagnostic test and they were
93 recruited to participate in the exhaled breath aspect of the study that also involved the collection
94 of saliva and MTS [14]. On each day of sample collection, participants answered an online
95 questionnaire to update their current symptoms and medications. For those who reported having
96 any symptom, they also reported their symptom onset date (i.e., “When did you begin to feel
97 sick?”).

98
99 The symptoms checklist in the baseline and follow-up questionnaires, as previously described
100 [14], included runny nose, stuffy nose, sneezing, sore throat, earache, malaise, headache, muscle

101 and/or joint ache, sweat/feverish/chills, nausea, loss of appetite, vomiting, abdominal pain or
102 diarrhea, chest tightness, shortness of breath, and cough. Participants self-reported for each of
103 these 16 symptoms on a scale of 0 to 3 (0 = “no symptoms,” 1 = “just noticeable,” 2 = “clearly
104 bothersome from time to time, but didn’t stop me from participating in activities,” 3 = “quite
105 bothersome most or all of the time and stopped me from participating in activities”).

106
107 For saliva collection, participants were instructed to not eat or drink 30 minutes prior to the visit
108 and then collect approximately 0.5-1 mL of saliva drooled into a plastic collection tube. For
109 MTS collection, trained clinical staff inserted a mid-turbinate swab approximately 1.5-2 inches
110 into one of the participants’ nostrils, rotated once, and then withdrawn. This procedure was
111 repeated in the other nostril for a total of two MTS per participant per visit.

112 113 *Laboratory analyses*

114 Saliva samples were processed using the SalivaDirect method [8] as previously described [14].
115 Briefly, 50 μ L of individual saliva samples were treated with Proteinase K (New England
116 Biolabs), heated at 95°C for 5 minutes, and kept at 4°C. MTS from both nostrils were combined
117 and processed as previously described [14]. Briefly, total nucleic acid was extracted from 200 μ L
118 of MTS with MagMax Pathogen RNA/DNA Kit (Applied Biosystems) on KingFisher Duo Prime
119 (Thermo Fisher Scientific), following the manufacturers’ protocols. The sample was eluted in 50
120 μ L of Elution Buffer and kept at 4 °C. MS2 phage was spiked in each heat-treated saliva sample
121 and extraction to control for extraction and PCR failure. RT-PCR was set up on the same day;
122 each reaction consisted of 1X TaqPath 1-Step Master Mix, No ROX, 1X TaqPath COVID-19
123 Real Time PCR Assay Multiplex (both from Thermo Fisher Scientific), and 10 μ L of heat-
124 treated saliva or eluted nucleic acids. Each PCR plate contained a positive control provided in the
125 TaqPath COVID-19 Combo Kit (Thermo Fisher Scientific) and a no template control. A positive
126 sample was defined as having Ct (cycle threshold) values < 40 for at least two out of three
127 SARS-CoV-2 targets (ORF1ab, N gene, and S gene)[15]. The average Ct values of all positive
128 targets were used in the following analyses.

129 130 *Statistical analyses*

131 We analyzed only paired same-day saliva and MTS samples to ensure the comparability of the
132 two samples. Group comparisons were made between participants having a positive result for
133 either sample and those with both samples being negative. Continuous variables (age and BMI)
134 were compared using t-test, and categorical variables were compared using Chi-square test (sex
135 and chronic respiratory illness) and Fisher’s exact test (age group, race, and ever smoker).

136
137 To compare the Ct values from saliva and MTS, we conducted paired t-test and Bland-Altman
138 analysis, and calculated the coefficient of determination (i.e., R squared from linear regression)
139 and Pearson correlation coefficient. The Chi-square test was used to explore the relationship
140 between detection and sample types. Cohen’s Kappa was calculated to demonstrate the degree of
141 agreement between the two sample types.

142
143 For participants with a positive saliva or MTS sample, we used a generalized additive logistic
144 model [16] to estimate and plot the probability of having a positive result by days since symptom
145 onset for the two sample types. We also created a plot using the LOESS (locally weighted
146 smoothing) method with 95% confidence interval for the change of Ct values by days since

147 symptom onset for the two sample types. Logistic regression was used to estimate the relative
148 odds of detection of SARS-CoV-2 in saliva over specified intervals since symptom onset.

149

150 All the analyses were carried out using RStudio and R (version 4.0.4) [17].

151

152 *Ethics statement*

153 This study was approved by the University of Maryland Institutional Review Board and the
154 Human Research Protection Office of the Department of the Navy. Electronically signed
155 informed consent was obtained from all participants and questionnaire data were collected and
156 stored with REDCap [18].

157

158 *Results*

159 We enrolled 58 individuals with known close contact with an active COVID-19 case. Contacts
160 provided a total of 200 saliva and MTS pairs. The number of days of sample collection per
161 participant ranged from one to seven. Among the contacts, 14 (24%) had at least one positive
162 sample including 11 with both positive saliva and MTS samples over the course of follow-up.
163 One contact had only positive saliva on 3 out of 3 samples (on days -3, 0, and 1 post symptom
164 onset) and 2 had only positive MTS samples; one was positive on 2 of 2 swabs (on days 7 and
165 10) and one on 1 of 5 swabs (day 21, negative on days 14, 17, 19, and 24). Most of the positive
166 participants (92.9%) were symptomatic, whereas only one (2.3%) participant from the test
167 negative group reported symptoms. Symptomatic participants were enrolled -3 to 14 days since
168 symptom onset and gave samples for up to 24 days from onset of symptoms. Symptoms were
169 mild across the follow-up period. One participant had an oral temperature ≥ 38 °C at the time of
170 sampling; three in total had temperatures ≥ 37.8 °C, and six in total had temperatures ≥ 37.5 °C;
171 all were in the positive group. No other significant differences were identified between the
172 positive and negative groups (Table 1).

173

174 *Viral RNA detection in and agreement between saliva and MTS*

175 Among 200 pairs of saliva and MTS samples we detected viral RNA in 32 (16%) of the saliva
176 and 29 (14.5%) of the MTS samples. The frequency of detection was similar for both sample
177 types ($p=0.781$) (Table S1). Cohen's Kappa demonstrated substantial agreement ($\kappa=0.83$) with
178 26 (14%) positive and 165 (82.5%) negative sample pairs (Table 2). The 14 participants who
179 became positive by either sample type during the follow-up period provided 41 saliva-MTS
180 sample pairs, among which 71% of MTS and 78% of saliva samples were positive (Table S2),
181 without respect to time since symptom onset. When focusing on positive participants, however,
182 the agreement was weak ($\kappa=0.43$ for all and $\kappa=0.42$ for those who were symptomatic) (Table S3a
183 and S3b).

184

185 *Comparison of Ct values between saliva and MTS*

186 Each RT-PCR reaction contained 10 μL of heat-treated saliva sample or RNA extracted from
187 MTS. Assuming no loss in the process, each reaction represented 7.78 μL of saliva sample or 40
188 μL of the MTS eluate. The Ct values for paired samples were highly correlated ($\rho = 0.84$, $r^2 =$
189 0.74 , Figure 1a). The Ct values for saliva were on average slightly but significantly greater than
190 for MTS samples (mean difference = 0.64, $p=0.01$) among all 58 participants (Figure 1b and
191 Figure S1), partially reflecting the difference in their input amounts.

192

193 *Relationship between days since symptom onset, sample types and probability of detection*

194 The Ct values among the positive symptomatic participants increased over time (day -3 through
195 24), indicating decreasing viral load. Saliva tended to have lower Ct values compared to MTS
196 from days -3 to 1.5, where MTS samples had lower Ct values thereafter (Figure 2A).

197
198 Among symptomatic participants who had one or more positive saliva or MTS samples, the
199 probability (sensitivity) of detecting viral RNA in saliva samples was 91% (10/11) from day -3
200 to day 2 (Table 3), was 89% (16/18) from day 3 through 8, and declined significantly thereafter
201 (Figure 2B and Figure S2). The probability of detecting virus in MTS samples from day -3
202 through day 2 was lower 45% (5/11), was 94% (17/18) from day 3 through 8, and then dropped
203 off again. Early in the course of infection (days -3 through 2) saliva had 12 times the odds of
204 being positive compared to MTS (Odds ratio = 12, 95% CI: 1.2, 130). Although there was a
205 trend toward greater sensitivity using MTS than saliva samples after day 2 post onset of
206 symptoms, the difference was not statistically significant (Table 3).

207
208 *Asymptomatic case*

209 Only one participant from our study population was an asymptomatic case. They provided one
210 pair of saliva and MTS samples, both of which were positive, with an average Ct value of 25.8
211 for MTS and 34.7 for saliva (Table S4).

212
213
214 *Discussion*

215 Early in the course of infection, saliva was significantly more sensitive than mid-turbinate nasal
216 swabs (MTS). We found that the optimal performance of saliva was in the pre-symptomatic
217 period and was more sensitive than MTS before symptom onset. Several studies have shown that
218 pre-symptomatic transmission plays a more important role than symptomatic and asymptomatic
219 transmission in the spread of SARS-CoV-2 [12,13]. Furthermore, saliva tended to have lower Ct
220 values compared to MTS from the pre-symptomatic period through the first few days post
221 symptom onset. Together, these findings suggest that saliva may be the preferred sample for
222 detecting SARS-CoV-2 early during the course of infection.

223
224 The CDC and the Infectious Disease Society of American recommendations for COVID-19
225 testing allow MTS, NPS, oral swabs, anterior nasal swabs, and saliva swabs as well as
226 saliva.[1,19] Some studies have shown differences in the sensitivity between NPS and MTS. In
227 older, more acutely ill populations, NPS appears to be more sensitive than MTS, especially later
228 in the course of illness (greater than 7 days) [4,9]. In a study of ambulatory and symptomatic
229 participants whose ages were more evenly distributed, NPS and MTS swabs were highly
230 correlated with a mean of 7 days since onset of symptoms [20]. Congrave-Wilson et al., in
231 agreement with the current study, found that saliva had the highest sensitivity in the first seven
232 days post COVID-19 onset when using NPS as the reference [2]. Becker et al. compared the
233 sensitivity of saliva and NPS for detecting COVID-19 in a convalescent cohort 8-56 days since
234 first symptom and found that NPS performed better [21]. They also showed that saliva was about
235 30% less sensitive than NPS in a diagnostic cohort, however, days since symptom onset were not
236 reported, so we cannot make direct comparison with our findings. Finally, a systematic review
237 by Bastos et al. found that saliva had similar sensitivity to NPS and costs less [11].

238

239 Our findings have implications for improving public acceptance of COVID-19 testing, reducing
240 the cost of mass COVID-19 screening, and improving the safety of healthcare workers who
241 conduct testing. These findings are extremely important when considering large-scale screening
242 of COVID-19 in schools and workplaces. In addition to its higher sensitivity in the early stage of
243 the disease as demonstrated in our data, saliva has quite a few other advantages that make it an
244 appealing screening tool. Saliva collection is less invasive and more acceptable to the general
245 population [7,22]. One of the barriers hindering COVID-19 testing is people's fear of nasal
246 swabs due to misinformation [23]. Also, the discomfort brought by nasal swabs may also reduce
247 people's willingness to get tested regularly, especially among children [24,25]. With the use of
248 saliva, screening in large groups with increased frequency may be more practicable. Saliva is
249 cheaper than swab-based methods, especially if pooled samples are used [11,26]. Bastos et al.
250 estimated that when sampling 100,000 individuals, using saliva saved more than \$600,000 in
251 comparison to using NPS [11]. These cost savings are especially important in the context of low
252 resource settings.

253
254 Saliva collection is also safer for healthcare workers (HCWs). Amid the pandemic, one of the
255 key concerns among HCWs is the occupational exposure to SARS-CoV-2 aerosols during some
256 medical procedures [27]. The collection of nasal swabs introduces such exposure via the close
257 interaction between patients and HCWs and by patients' coughing and sneezing as a result of the
258 procedures [28]. In contrast, saliva is the only upper respiratory specimen suggested by the CDC
259 that can be self-collected without supervision [1] and hence protects HCWs from directly
260 contacting the patients when the samples are being collected. Given all these advantages of
261 saliva compared to NPS, our findings further support the use of saliva for large-scale screening,
262 especially of pre-symptomatic patients.

263
264 The current study has several limitations. The contacts enrolled in this study who eventually
265 tested positive for SARS-CoV-2 developed mild, and in some cases, transient infections. Some
266 of these mild (low viral titer) infections would not have been detected by less frequent testing
267 protocols and may not have posed a risk for onward transmission. The sample size of those who
268 tested positive is relatively small. Only one asymptomatic case was identified in our study so we
269 could not compare the sensitivity of the two types of samples among asymptomatic COVID-19
270 cases. The evidence for using saliva to detect asymptomatic cases was mixed in previous studies
271 [2,10] and further studies are needed to clarify this issue.

272
273 In conclusion, the use of saliva is preferable for testing pre-symptomatic populations. It is more
274 acceptable to people, which reduces barrier to testing. It is also more cost effective for
275 individuals to collect their own saliva rather than using highly trained professionals to collect
276 NPS and/or MTS. Finally, self-collected saliva samples eliminate the exposure to aerosols
277 produced by sneezing, coughing and gagging of patients undergoing NPS/MTS.

387 Tables

388

389 Table 1. Characteristics of the study population

	Never positive	Positive for MTS or saliva	All participants	
Number of participants	44	14	58	
Number of sample pairs	159	41	200	
Number of days of sample collection per participant, median (range)	4 (1, 7)	3 (1, 6)	3 (1, 7)	
Female, N (%)	20 (46)	8 (57)	28 (48)	
Age, mean \pm SD	26.5 \pm 15.5	27.3 \pm 13.8	26.7 \pm 15	
Age group, N (%)				
<18	2 (4)	1 (7)	3 (5)	
18-45	38 (86)	11 (79)	49 (84)	
>45	4 (9)	2 (14)	6 (10)	
White, N (%)	30 (68)	11 (79)	41 (71)	
BMI, mean \pm SD	25.6 \pm 4.9	25.2 \pm 4.4	25.5 \pm 4.7	
Chronic respiratory illness ^a , N (%)	17 (39)	5 (36)	22 (38)	
Ever smoker, N (%)	1 (2)	1 (7)	2 (3)	
Ever symptomatic ^b , N (%)	1 (2)	13 (93)	14 (24)	
Symptomatic participants	Days since symptom onset at enrollment, median (range)	2 (-)	3 (-3, 14)	2.5 (-3, 14)
	Overall days since symptom onset of sample collection, median (range)	6.5 (2, 12)	5 (-3, 24)	5 (-3, 24)
	Loss of taste/smell, N (%)	0	2 (15)	2 (14)
	Median upper ^c respiratory symptoms (IQR)	3 (1.2, 6.2)	2 (0, 3)	2 (0.2, 3)
	Median lower respiratory symptoms (IQR)	0 (0, 0)	0 (0, 1)	0 (0, 1)
	Median systemic symptoms (IQR)	0.5 (0, 1.8)	0 (0, 1.2)	0 (0, 1.8)
	Median gastrointestinal symptoms (IQR)	0 (0, 0)	0 (0, 0)	0 (0, 0)
	Temperature, mean Celsius \pm SD	37 \pm 0.3	37.2 \pm 0.5	37.2 \pm 0.4

390 ^a Chronic respiratory illness = volunteers with any Chronic obstructive pulmonary disease,
 391 Asthma, Other lung diseases.

392 ^b Group comparison, p<0.05.

393 ^c Symptoms at the time of each sample collection visit. Sixteen individual symptoms were rated
394 from 0 to 3. Systemic (max score of 12) = malaise + headache + muscle/joint ache +
395 sweats/fever/chills; Gastrointestinal (max score of 12) = loss of appetite + nausea + vomit +
396 diarrhea; Lower Respiratory (max score of 9) = chest tightness + shortness of breath + cough;
397 Upper Respiratory (max score of 15) = runny nose + stuffy nose + sneeze + earache + sore
398 throat.

399

400

401

402 Table 2. Viral RNA detection in paired saliva and MTS samples from all participants (N=58) ^a

<i>Saliva Positive</i>	<i>MTS Positive</i>		<i>Total</i>
	No	Yes	
No	165	3	168
Yes	6	26	32
<i>Total</i>	171	29	200

403 ^a $\kappa=0.83$

404

405 Table 3. Sensitivity of saliva and MTS and relative odds of detection of SARS-CoV-2 in saliva
406 by day since symptom onset among 13 mildly symptomatic contacts of known cases

Days since symptom onset^a	Saliva Positive/N (Sensitivity %)	MTS Positive/N (Sensitivity %)	Odds Ratio Saliva:MTS	p-value
-3 through 2	10/11 (91)	5/11 (45)	12 (1.2, 130)	0.04
3 through 8	16/18 (89)	17/18 (94)	0.47 (0.037, 6)	0.55
9 through 24	5/11 (45)	6/11 (55)	0.7 (0.13, 3.8)	0.67

407 ^a Days since symptom onset inclusive of the start and end day

408

409 Figure Legends

410

411 Figure 1. Association between Ct values of saliva and MTS samples among 58 participants and
412 400 samples

413 A. Scatter plot of Ct values of saliva and MTS

414 B. Bland-Altman plot for comparison of saliva and MTS

415

416 Figure 2. The change of Ct values and probability of testing positive by days since symptom
417 onset. Data are for MTS and saliva samples from 13 participants who provided a total of 40 pairs
418 of samples and had one or more samples positive for SARS-CoV-2 RNA.

419 A. Change of Ct values by days since symptom onset,

420 B. Probability of being tested positive by days since symptom onset estimated from a generalized
421 additive logistic model.
