16 **Abstract**

17 Comprehensive data on transmission mitigation behaviors and SARS-CoV-2 infection  
18 and serostatus are needed from large, community-based cohorts to identify SARS-CoV-2 risk  
19 factors and impact of public health measures. From July 2020 to March 2021, ≈5,500 adults from  
20 the East Bay Area, California were followed over three data collection rounds. We estimated the  
21 prevalence of antibodies from SARS-CoV-2 infection and COVID-19 vaccination, and self-  
22 reported COVID-19 test positivity. Population-adjusted SARS-CoV-2 seroprevalence was low,

23 increasing from 1.03% (95% CI: 0.50-1.96) in Round 1 (July-September 2020), to 1.37% (95%  
24 CI: 0.75-2.39) in Round 2 (October-December 2020), to 2.18% (95% CI: 1.48-3.17) in Round 3  
25 (February-March 2021). Population-adjusted seroprevalence of COVID-19 vaccination was  
26 21.64% (95% CI: 19.20-24.34) in Round 3. Despite >99% of participants reporting wearing  
27 masks, non-Whites, lower-income, and lower-educated individuals had the highest SARS-CoV-2  
28 seroprevalence and lowest vaccination seroprevalence. Our results demonstrate that more  
29 effective policies are needed to address these disparities and inequities.

## 30 **Introduction**

31 The first confirmed severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2)  
32 infection in the California Bay Area was reported on February 28, 2020.(1) In response,  
33 measures to prevent transmission were implemented soon after and included shelter-in-place  
34 orders, mask mandates, business and school closures, and social distancing recommendations.  
35 Despite these measures, spikes in reported infections occurred from July to September 2020 and  
36 December 2020 to February 2021.(2)

37 Local public health and healthcare systems experienced major challenges in preventing  
38 infections, identifying COVID-19 cases, and ensuring adherence to transmission mitigation  
39 strategies. Furthermore, disparities and inequities in COVID-19 have been observed in the  
40 United States(3) and there are few studies investigating the association of risk behaviors with  
41 infection outcomes at the individual level.(4–6) A detailed understanding of the effectiveness of  
42 transmission mitigation behaviors and sociodemographic factors that contribute to the  
43 disproportionate impact of COVID-19 in vulnerable communities is critical. Public health and policy  
44 directives aimed at controlling ongoing transmission, developing future prevention strategies,

45 and targeting health disparities and inequities must evidence-based. Large population-  
46 representative cohorts with individual-level data on social and behavioral factors(7) associated  
47 with COVID-19 and SARS-COV-2 infection and serostatus(8–12) are needed.

48 To address this need, we investigated individual-level characteristics and mitigation  
49 behaviors that contributed to SARS-CoV-2 seroprevalence, self-reported infection, and viral  
50 infection, and other outcomes in a large, population-based sample of over 5,500 individuals from  
51 12 East Bay cities in Northern California followed longitudinally. During three time periods  
52 from July 2020 to April 2021, we estimated the population-adjusted prevalence of SARS-CoV-2  
53 outcomes and differences by age, sex, race/ethnicity, ZIP code, and other demographic strata as  
54 well as the effect of transmission mitigation behavior on SARS-CoV-2 prevalence.

## 55 **Methods**

### 56 *Recruitment and participants*

57 Recruitment and selection of study participants was completed using a screening phase  
58 followed by a longitudinal study phase with three rounds of data collection (Figure 1). In the  
59 screening phase, all residential addresses within the East Bay cities and communities of Albany,  
60 Berkeley, El Cerrito, El Sobrante, Emeryville, Hercules, Kensington, Oakland, Piedmont, Pinole,  
61 Richmond, and San Pablo (~307,000 residential households) were mailed an invitation to  
62 complete a consent form and screening questionnaire. In a household, the individual aged 18  
63 years or older with the next birthday was eligible to participate. Additional eligibility criteria  
64 included living within the study region, willingness to provide biospecimens and questionnaire  
65 responses, ability to read and speak English or Spanish, and having internet access and an email  
66 address.

67           The target sample size was 5,500 participants. The distribution of racial and ethnic  
68   identification in the screening questionnaire responses was more White and non-Hispanic than  
69   the region population. To obtain a sample that resembled the racial and ethnic proportions in the  
70   2018 American Community Survey (ACS) for the study region, we ranked assigned ranks for  
71   order of inclusion to all eligible individuals who responded to the screening questionnaire. Black  
72   and/or Hispanic individuals were ranked the highest followed by other non-Whites. Order of  
73   inclusion for Whites was randomly sampled. In Round 1, individuals ranked between 1 and  
74   5,500 were offered study enrollment. Those who declined to enroll were replaced with next  
75   highest ranked individuals who had not been offered study entry. In subsequent rounds,  
76   individuals who had participated in the previous round(s) were offered participation in the next  
77   round. If participation was declined, individuals from the pool of participants who had not  
78   participated in a study round were invited. Approximate dates for each round were July-  
79   September 2020, October-December 2020, and February-March 2021.

80           All participants provided their informed consent for the screening phase. All participants  
81   in the study phase provided their informed consent for each study round. The study was  
82   approved by the University of California, Berkeley Committee on Protection of Human Subjects  
83   (Protocol #2020-03-13121).

#### 84   *Study procedures*

85           At the start of each round, eligible participants were invited to participate. Those who  
86   agreed to participate received a kit via FedEx containing materials for self-collection of  
87   biospecimens, pre-paid return shipping labels, and instructions to complete an online-  
88   administered questionnaire at the same time as biospecimen collection.

#### 89   *Questionnaire*

90 The questionnaire addressed sex, gender, age, race/ethnicity, income, employment,  
91 physical and mental health, as well as symptoms potentially related to COVID-19 within the  
92 previous 2 weeks, and SARS-CoV-2 testing outside of the study. Participants were also asked  
93 about behaviors that might affect risk of SARS-CoV-2 infection including physical distancing  
94 practices, close contacts with others, and mask wearing. Questionnaires were available in  
95 English or Spanish.

#### 96 *SARS-CoV-2 viral and antibody testing*

97 Anterior nasal nare swabs for viral RNA testing and dried blood spots (DBS) for antibody  
98 testing were collected from participants at each study round. Quantitative reverse transcription  
99 PCR (RT-qPCR) was used to identify SARS-CoV-2 viral infection. Three tests were used to  
100 assess anti-SARS-CoV-2 antibodies in DBS: Ortho VITROS® Anti-SARS-CoV-2 Total IgG and  
101 spike IgG ELISA targeted antibodies against the SARS-CoV-2 spike protein (indicating prior  
102 natural infection or vaccination), and Roche-NC Total IgG targeted antibodies against the  
103 nucleocapsid (NC) protein (indicating prior natural infection only).(13) Before COVID-19  
104 vaccines were available in the study region during rounds 1 and 2, detection of antibodies against  
105 the SARS-CoV-2 spike protein was considered evidence of SARS-CoV-2 infection. During  
106 Round 3, vaccinations were widely available, therefore detection of antibodies against the NC  
107 protein were considered evidence of SARS-CoV-2 infection, while detection of antibodies  
108 against the spike protein were considered evidence of SARS-CoV-2 infection or COVID-19  
109 vaccination (Supplement S-4.2, Figure S-1).

#### 110 *SARS-CoV-2 outcomes*

111 The following outcomes were investigated in each round: (1) cumulative SARS-CoV-2  
112 antibody positivity, (2) participants' self-reported history of SARS-CoV-2 positivity from RT-

113 qPCR testing outside the study, (3) and a surveillance definition of “probable COVID-19 case”  
114 derived from self-reported symptoms and close contact with infected individuals(14), and (4)  
115 viral SARS-CoV-2 positivity from RT-qPCR testing of nasal swabs (Supplement 4.2). We also  
116 investigated antibodies induced by COVID-19 vaccination only in Round 3. SARS-CoV-2  
117 antibody positivity was defined as having detectable antibodies in the current and/or previous  
118 round(s). DBS samples that tested both negative for anti-NC antibodies and positive for anti-  
119 spike antibodies in Round 3 were considered to have antibodies from COVID-19 vaccination  
120 alone. Self-reported COVID-19 viral positivity prevalence was defined as the proportion of  
121 participants reporting a positive viral test among all participants who reported being tested within  
122 a study round. Probable COVID-19 case prevalence was defined as the proportion of participants  
123 identified as a probable COVID-19 case among all participants who provided valid responses  
124 within a study round. Viral positivity prevalence was defined as testing positive by RT-qPCR  
125 from nasal swab samples.

## 126 **Statistical analysis**

### 127 *Population-adjusted seroprevalence and other SARS-CoV-2 outcomes*

128 Bayesian multilevel regression and poststratification (MRP) was used to estimate  
129 population-adjusted cumulative seroprevalence, self-reported SARS-CoV-2 viral positivity  
130 prevalence at each study round, and “probable COVID-19” prevalence at each study round. MRP  
131 is a regression-based method for estimating population and sub-population averages from survey  
132 data that has been shown to perform better than survey weighting, particularly with sparse data  
133 (15,16).

134 In addition to estimation of regional prevalence of our outcomes, we estimated  
135 prevalence within demographic groups and geographic areas in the study region. Variables of

136 interest were gender, age, race, Hispanic ethnicity, income, education, household size, and ZIP  
137 code. We used a method described by Leeman and colleagues to generate a synthetic population  
138 for poststratification using data from the 2018 American Community Survey (ACS) and the  
139 Public Use Microdata Sample (PUMS).(16) Poststratification was done using binary sex because  
140 gender is not reported by the ACS. Race and ethnicity were combined into a single variable to  
141 reduce the number of poststratification strata.

142 At each study round, binary SARS-CoV-2 outcomes were modeled as a function of  
143 geographic and demographic characteristics using multilevel logistic regression models.  
144 Participant sex was included as a fixed effect. Vectors of random intercepts were defined for  
145 each category of race/ethnicity, age, education, income, household size, and ZIP code and two-  
146 way interactions between ZIP code, race/ethnicity, educational attainment, income, and age. To  
147 improve estimation of geographic effects we allowed for spatial correlations using the modified  
148 Besag-York-Mollie model and included the proportion of Spanish speaking households within  
149 the ZIP code of residence from the ACS as a fixed effect (Supplement S-6).(17)

#### 150 *SARS-CoV-2 outcome prevalence and measures of association*

151 We report populated-adjusted prevalence of SARS-CoV-2 outcomes across the study  
152 region and within geographic and demographic groups of interest. To calculate prevalence  
153 estimates, posterior distributions of the relevant poststratification stratum were aggregated. We  
154 also estimated prevalence differences (PD) and prevalence ratios (PR) for the association  
155 between populated-adjusted SARS-CoV-2 outcomes and race/ethnicity, education, and sex. For  
156 each parameter of interest, the mean of the posterior distribution was the point estimate, and the  
157 95% credible interval (CI) was the 2.5% and 97.5% quantiles of a posterior distribution.

#### 158 *SARS-CoV-2 test-kit bias corrected seroprevalence*

159 We estimated cumulative SARS-CoV-2 seroprevalence at each study round adjusted for  
160 the net sensitivity and specificity of the SARS-CoV-2 antibody testing algorithm in each study  
161 round (Supplement S-6).

### 162 *Transmission mitigation behavior analyses*

163 In each round, participants were asked about physical distancing practices, recent close  
164 contacts with others, mask wearing, and other behaviors and activities that might affect the risk  
165 of SARS-CoV-2 infection. We classified participants into two behavior categories, “high-risk”  
166 and “low-risk”, with those responses using latent class analysis.(18) Crude associations between  
167 behavior categories and characteristics such as sex, age, race/ethnicity, education, and income  
168 were assessed with  $\chi^2$  tests. Associations between high-risk vs. low-risk behavior and within  
169 round SARS-CoV-2 seroprevalence and self-reported test positivity were estimated using the  
170 MRP model described above with random intercepts for behavior categories and interactions  
171 between the behavior categories and ZIP code, age, race/ethnicity, education, and income  
172 (Supplement S-5 and S-6).

173 Statistical analyses were completed in R 4.0.2. NIMBLE was used to implement MRP  
174 models.(19) Detailed descriptions of MRP methods and code are provided in Supplementary  
175 Methods and at [github.com/adams-cam/ebcovid\\_prev](https://github.com/adams-cam/ebcovid_prev).

## 176 **Results**

### 177 *Enrollment and characteristics of study participants*

178 Of the 16,115 residents who consented and completed the screening procedures between May-  
179 July 2020, 1,777 did not satisfy inclusion criteria and were excluded (Figure 1). Characteristics  
180 of participants are presented in Table 1 and Table S-1. Participation rates were high (Round 1:  
181 76.8%, Round 2: 89.8%, and Round 3: 87.3%), and participants identified predominantly as

182 female (~63%). Those aged 45-64 years were the largest age group of participants across all  
183 study rounds (ranging from 37.3% to 39.4%). Most participants identified as White (52.5% to  
184 63.3%), followed by Asian/Pacific Islander (13.9% to 15.7%), Hispanic (11.0% to 15.6%), two  
185 or more races (6.9% to 9.1%), African American or Black (3.0% to 4.9%), and Native  
186 American/Alaska Native or other (1.7% to 2.2%).

187       Of those who completed the questionnaire, 87.3%, 95.3%, and 96.6% provided DBS and  
188 93.6%, 98.1% and 98.% provided nasal swabs in rounds 1, 2, and 3, respectively (Table 2).  
189 Antibodies against the SARS-CoV-2 spike protein were detected in 29 (0.6%) and 33 (0.6%) of  
190 DBS in rounds 1 and 2, respectively. In Round 3, NC antibodies from natural infection alone  
191 were detected in 84 participants (1.8% of 4,806) and spike antibodies from natural infection or  
192 vaccination were detected in 1,452 participants (31.3% of 4,806). Viral infection was detected in  
193 less than three nasal swabs in each round. The proportion of participants reporting both receiving  
194 a SARS-CoV-2 test outside the study and testing positive within a study round increased over the  
195 study period; 10/1,030 (1.0%) participants reporting a positive COVID-19 result in Round 1,  
196 19/2,059 (0.9%) in Round 2, and 53/1892 (2.8%) in Round 3. In all rounds, few participants met  
197 the criteria for being a COVID-19 probable case (<0.5%) (Table S-2).

#### 198 *Population adjusted SARS-CoV-2 outcome prevalence in study region*

199       Population adjusted SARS-CoV-2 seroprevalence, self-reported COVID-19 test  
200 positivity, and probable COVID-19 cases are reported in Table 3. Overall, populated-adjusted  
201 SARS-CoV-2 natural infection seroprevalence was low across the study region: Round 1 (July-  
202 September 2020) 1.03% (95% CI 0.50-1.96), Round 2 (October-December 2020 1.37% (0.75-  
203 2.39), and Round 3 (February-March 2021) 2.18% (95% CI 1.48-3.17). In Round 3 the  
204 populated-adjusted seroprevalence of COVID-19 vaccination was 21.64% (95% CI: 19.2, 24.34).

205 Models incorporating sensitivity and specificity of the antibody assays yielded lower SARS-  
206 CoV-2 seroprevalence estimates in Round 1, similar estimates in Rounds 2 and 3, and a higher  
207 estimate of COVID-19 vaccine seroprevalence in Round 3. Population adjusted self-reported test  
208 positivity to SARS-CoV-2 was similar in Rounds 1 (1.11%, 95 CI: 0.39-2.40) and 2 (1.29%,  
209 95% CI: 0.55, 2.17) to seroprevalence estimates and increased to 4.58% (95% CI: 2.56-7.64) in  
210 Round 3. Population-adjusted prevalence of being a COVID-19 probable case was <1% across  
211 rounds (Figure S-2).

### 212 *SARS-CoV-2 seroprevalence and infection vary by geographic area*

213 There was evidence for spatial differences in both population-adjusted seroprevalence and  
214 self-reported test positivity (Figure 2). The northern areas (Richmond, San Pablo, Pinole, and  
215 Hercules) and southern areas (East Oakland) of the study region had higher seroprevalence than  
216 Berkeley, El Cerrito, and North/Downtown Oakland. Self-reported test positivity was also higher  
217 in the northern and southern areas. These trends were consistent across study rounds.

### 218 *Population adjusted seroprevalence and self-reported test positivity prevalence within subgroups*

219 Differences in population-adjusted seroprevalence were observed among demographic  
220 groups (Figure 3). In Round 1, those aged less than 45 years had higher likelihood of antibody  
221 positivity than those aged 45 or older, but this relationship reversed over time (Figure 3B). In  
222 general, non-Whites consistently had a higher likelihood of antibody positivity than Whites  
223 (Figure 3C). The likelihood of antibody positivity also differed by household income and  
224 educational attainment, with those reporting a household income <\$100,000 and less than a  
225 college degree having a higher likelihood of antibody positivity than their comparison groups  
226 (Figures 3D-E). Those in households with more than four people had a higher likelihood of  
227 antibody positivity than those in households with four or less people (Figure 3F). There was no

228 clear relationship between sex and population-adjusted seroprevalence (Figure 3A). Similar  
229 relationships were seen between demographic groups and self-reported test prevalence (Figure S-  
230 3).

### 231 *COVID-19 vaccination seroprevalence differs by race/ethnicity and age*

232 In Round 3, population-adjusted COVID-19 vaccination seroprevalence was lower in all  
233 non-White groups compared to Whites, (White vs. Non-White, PD: -4.35%, 95% CI: (-9.32, -  
234 0.35), Figure 4, Table 4). The difference between racial/ethnic groups was largest among older  
235 participants; non-Whites had a lower COVID-19 vaccination seroprevalence compared to Whites  
236 among those aged between 65-74 (PD: -11.67%, 95% CI: (-20.98, -2.49)) and those aged 75 or  
237 older (PD: -10.15%, 95% CI: (-22.25, 0.43)).

### 238 *Mask-wearing and association between high-risk vs. low-risk behavior and seroprevalence*

239 More than 99% of participants reported ever wearing a mask 99% reported wearing a  
240 mask during leisure and exercise activities, >91% reported wearing a mask at work, and >88%  
241 reported wearing a mask while shopping (Table S-3). After clustering participants into “low-  
242 risk” and “high-risk” groups according to self-reported mitigation behaviors, most participants  
243 were considered low-risk across the study rounds (70%, 82%, and 77%, respectively; Figure  
244 5A). Behaviors with the largest differences in high- versus low-risk behavior were reporting  
245 “yes” to: left the house for work, medical/healthcare, care of relative, or other, worked with  
246 potential COVID-19 contact, attended a gathering, and traveled to county outside of residence  
247 within last two weeks (Figure 5B). Age, race/ethnicity, and education were all associated  
248 ( $p < 0.001$ ) with high- vs. low-risk groups (Table S-4), but we did not observe strong evidence for  
249 an association between mitigation behavior and either seroprevalence or self-reported test

250 positivity (Table 5), although the point estimates indicate that “low-risk” behavior was  
251 associated with lower seroprevalence.

## 252 **Discussion**

253 In the current study, we investigated individual-level characteristics and behaviors that  
254 contributed to SARS-CoV-2 related outcomes, including seroprevalence and self-reported  
255 infection, in a large, population-based sample of over 5,500 participants from 12 East Bay  
256 (Northern California) cities. During three time periods from July 2020 to March 2021, we  
257 estimated the population-adjusted prevalence of SARS-CoV-2 outcomes across the study region  
258 and within strata of age, sex, race/ethnicity, ZIP code, and household size. We then characterized  
259 behaviors to mitigate transmission of SARS-CoV-2 and their effects on related outcomes.  
260 Overall, prevalence of SARS-CoV-2 outcomes for natural infection were low which may be  
261 attributable to the high percentage of mask-wearing and other risk-mitigating behaviors among  
262 our participants. COVID-19 vaccination seroprevalence estimates in Round 3 was greater than  
263 20%, with non-Whites having much lower seroprevalence than Whites.

264 Despite the low overall SARS-CoV-2 seroprevalence and infection observed in our study,  
265 ZIP code of residence, age, racial/ethnic identification, education, and income all contributed to  
266 differences in seroprevalence. Specifically, non-Whites, those without a college degree, and  
267 lower income households, had higher seroprevalence. Further, ZIP codes with higher proportions  
268 of Spanish speakers had higher population-adjusted seroprevalence estimates (Figure S-4). These  
269 differences persisted despite the high rates of mask wearing reported by our study sample,  
270 further adding to strong evidence that the risk of COVID-19 is distributed unequally and that  
271 structural inequities play an important role in COVID-19 risk.(20–23) Moreover, during Round 3  
272 (February-March 2021), COVID-19 vaccines were widely available across the study region. We

273 found that Whites had much higher prevalence of antibodies against the SARS-CoV-2 spike  
274 protein in Round 3, indicative of vaccination status, than non-Whites, as reported  
275 elsewhere.(3,24) Notably, this difference was largest among those aged 65 or older. These  
276 findings demonstrate that in the first few months of vaccine availability in the Bay Area, large  
277 disparities in vaccination rates by race/ethnicity were observed among older persons, and Whites,  
278 the group with the lowest prevalence of SARS-CoV-2 infection, were more likely to be  
279 vaccinated, further underscoring the inequities that exist surrounding the coronavirus pandemic.

280 Another key finding was that almost all participants reported wearing masks. This  
281 contrasts with models of mask usage reported by the Institute for Health Metrics and Evaluation  
282 which reported mask usage ranging between 75-82% from December 2020 through March 2021  
283 in California.(25,26) Mask wearing is one the most effective behaviors for controlling  
284 community spread of SARS-CoV-2 infection.(27) The high rate of mask usage by study  
285 participants may partially explain why we did not detect a differences between high-risk and  
286 low-risk mitigation behavior and SARS-CoV-2 prevalence, and partially explain why our  
287 estimates of SARS-CoV-2 seroprevalence and self-report test positivity were lower than public  
288 case reports. However, a recent study estimating SARS-CoV-2 seroprevalence from blood  
289 donors reported seroprevalence in the Bay Area region of California that were similar to our  
290 estimates through December 2020.(28)

291 A major strength of this study was the longitudinal design and collection of individual-  
292 level data, including biospecimens for antibody and virus testing, which is challenging but much  
293 needed in current studies of the pandemic. Comprehensive data on social distancing, self-  
294 quarantine, mask wearing, working from home, and other public health and SARS-CoV-2  
295 mitigation efforts are needed to inform current and future strategies of prevention and for whom

296 to target prevention efforts. At-home collection of biospecimens, including dried blood spots for  
297 antibody testing, made it possible to regularly test participants without any in-person interaction.  
298 This was a critical feature, particularly early in the pandemic, when recommendations were to  
299 travel only for essential purposes and to limit in-person interactions. At-home sample collection  
300 was used to obtain more than 30,000 biospecimens and is a feasible approach for even larger  
301 populations and geographic regions.

302 One limitation of this study was the under-representation of certain demographics in our  
303 sample. Supplementary mailings of recruitment postcards in Spanish were sent to residences in  
304 ZIP codes with high proportions of Spanish speaking households. We also placed recruitment  
305 flyers in local grocery stores and conducted outreach to community organizations, local  
306 government officials, and school districts in the study region. Despite these efforts, non-Whites,  
307 males, lower income households, and individuals with lower education and from lower  
308 socioeconomic ZIP codes were underrepresented in our sample. Unhoused individuals were also  
309 not captured in our sample. This was important given evidence that individuals who identify as  
310 Hispanic or Black, and other underrepresented groups, are at the highest risk for COVID-19.(23)  
311 These discrepancies may have led to underestimation of overall SARS-CoV-2 seroprevalence  
312 and self-reported infection, although the MRP models may have somewhat minimized this effect  
313 by pooling information across similar observed characteristics in the sample data. Our  
314 seroprevalence estimates were consistent with weekly case prevalence reported by public health  
315 agencies in ZIP codes with high response rates (Figure S-5).(29) Additionally, there may be  
316 unmeasured confounding from variables not included in the analyses and self-selection bias from  
317 some participants in COVID-19 research who may be more fervent adherers to COVID-19

318 public health measures. Finally, some individuals do not seroconvert after infection or  
319 vaccination.

320 Our results underscore the substantial and persistent inequities that exist surrounding the  
321 coronavirus pandemic. Non-Whites, lower-income, and lower-educated individuals had the  
322 highest SARS-CoV-2 seroprevalence. This disparity in seroprevalence was observed despite near  
323 universal rates of mask wearing in our sample. We also observed large differences in COVID-19  
324 vaccination seroprevalence between racial and ethnic groups. More work must be done to  
325 address these disparities and inequities, such as allocation of resources for high-risk communities  
326 and strategies to mitigate the structural barriers posed by social and structural determinants of  
327 health.

75 +	54.01 (46.12, 61.79)	-10.15 (-22.25, 0.43)

\*CI, credible interval; PD, prevalence difference; Prev, prevalence.

†Population adjusted seroprevalence in round 3 estimated using multilevel regression and poststratification (MRP); Seroprevalence and 95% CI are the mean and 2.5% and 97.5% quantiles of a posterior distribution respectively. Assay used detects antibodies from natural SARS-CoV-2 infection or from COVID-19 vaccination.

‡Population adjusted COVID-19 seroprevalence difference in round 3 between each race/ethnicity group and Whites among race/ethnicity and between non-Whites and Whites within each age group. PDs estimated using MRP, and the PDs and 95% CIs are the mean and 2.5% and 97.5% quantiles of a posterior distribution, respectively. A

465

466

467 Table 5. Association between seroprevalence and self-reported test positivity and high-risk vs.  
468 low-risk mitigation behavior within each study round.

	MOA†	Round 1	Round 2	Round 3
SARS-CoV-2 antibody prevalence‡	PD % (95% CI)	-0.21 (-1.4, 0.79)	0.02 (-1.59, 1.03)	-0.46 (-2.23, 1.00)
	PR (95% CI)	0.93 (0.34, 2.03)	1.4 (0.32, 3.93)	0.88 (0.45, 1.57)
	PD % (95% CI)	0.53 (-0.73, 2.24)	0.11 (-2.12, 1.6)	-1.11 (-5.26, 2.18)
Self-reported test positivity	PR (95% CI)	2.17 (0.54, 6.72)	1.56 (0.33, 4.65)	0.87 (0.41, 1.64)

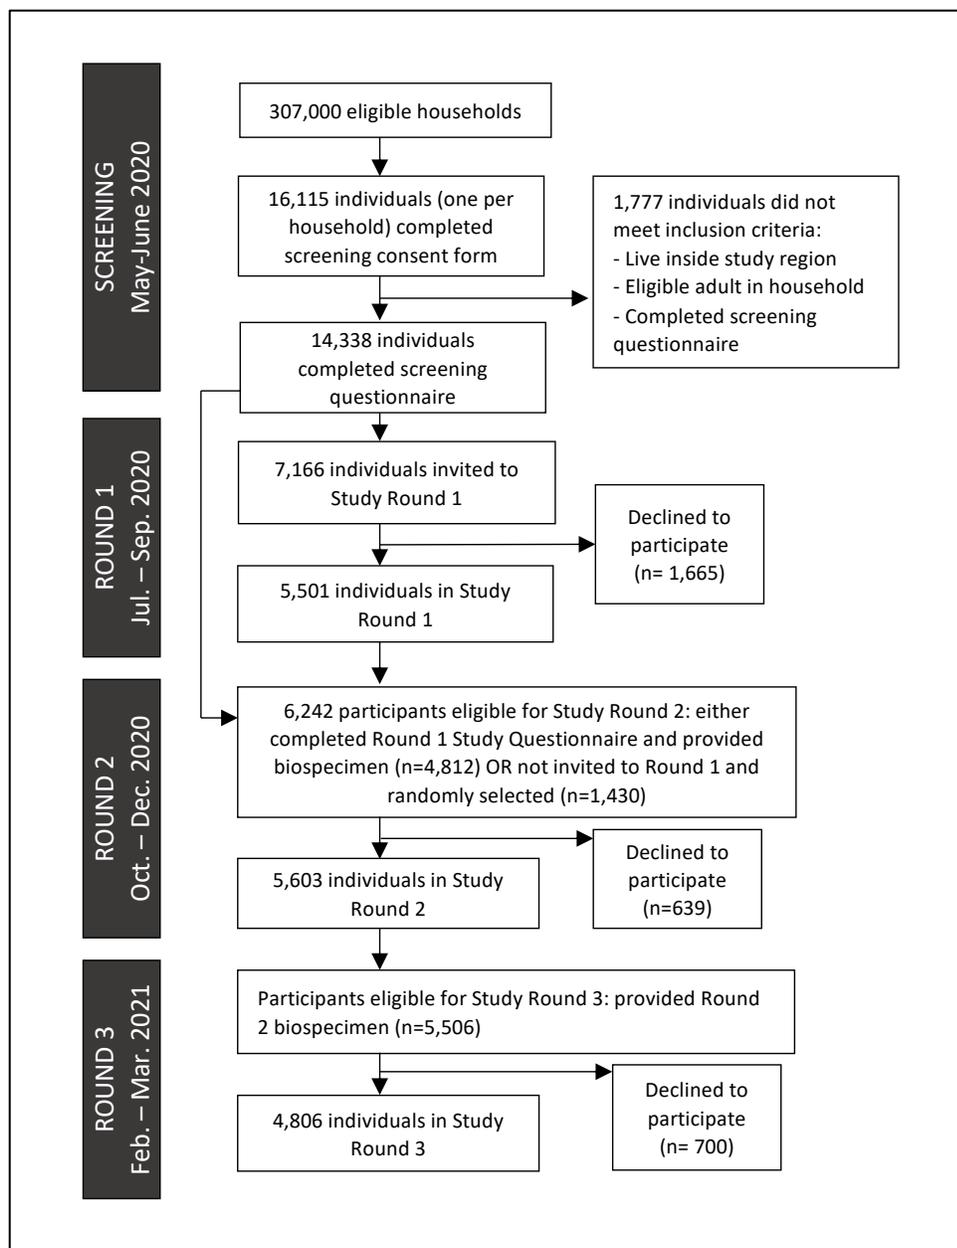

\*CI, credible interval; MOA, measure of association; PD, prevalence difference; PR, prevalence ratio

†Populated adjusted prevalence estimated using multilevel regression and poststratification models; point estimate is the mean of a posterior distribution of the parameter, 95% credible interval estimated from 2.5% and 97.5% quantiles of a posterior distribution.

‡Defined as having detectable SARS-CoV-2 antibodies within a study round.

473

474

475 Figure 2. Population adjusted, A) cumulative seroprevalence of SARS-CoV-2 antibodies to  
476 natural infection, and B) self-reported test positivity prevalence for (July 2020-April 2021)  
477 across the study region.

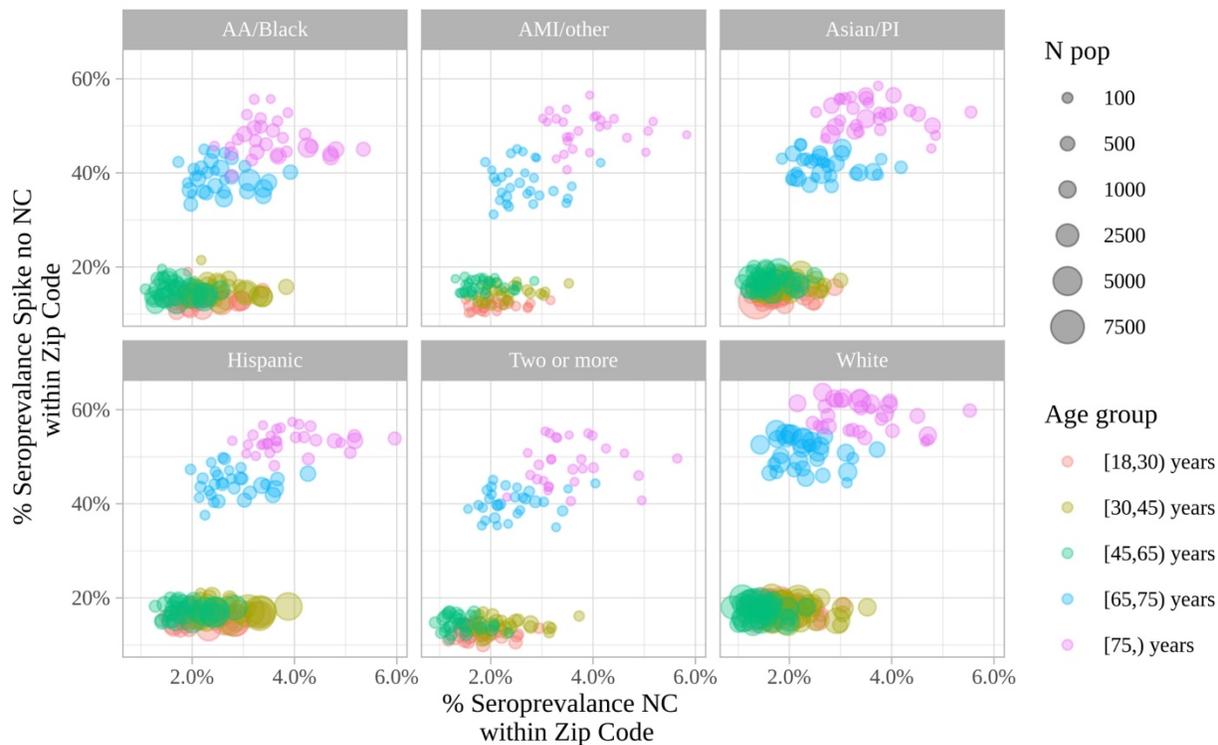

478

479

480 Figure 3. Cumulative seroprevalence of SARS-CoV-2 anti-S antibodies (Rounds 1 and 2) and  
 481 anti-NC antibodies (Round 3) (July 2020-April 2021) among demographic subgroups, A) sex, B)  
 482 age, C) race/ethnicity, D) income, E) education, and F) household size. Abbreviations: AA,  
 483 African American; AMI, American Indian; PI, Pacific Islander.

484

485

486 Figure 4. Round 3 population-adjusted nucleocapsid (natural infection) seroprevalence compared

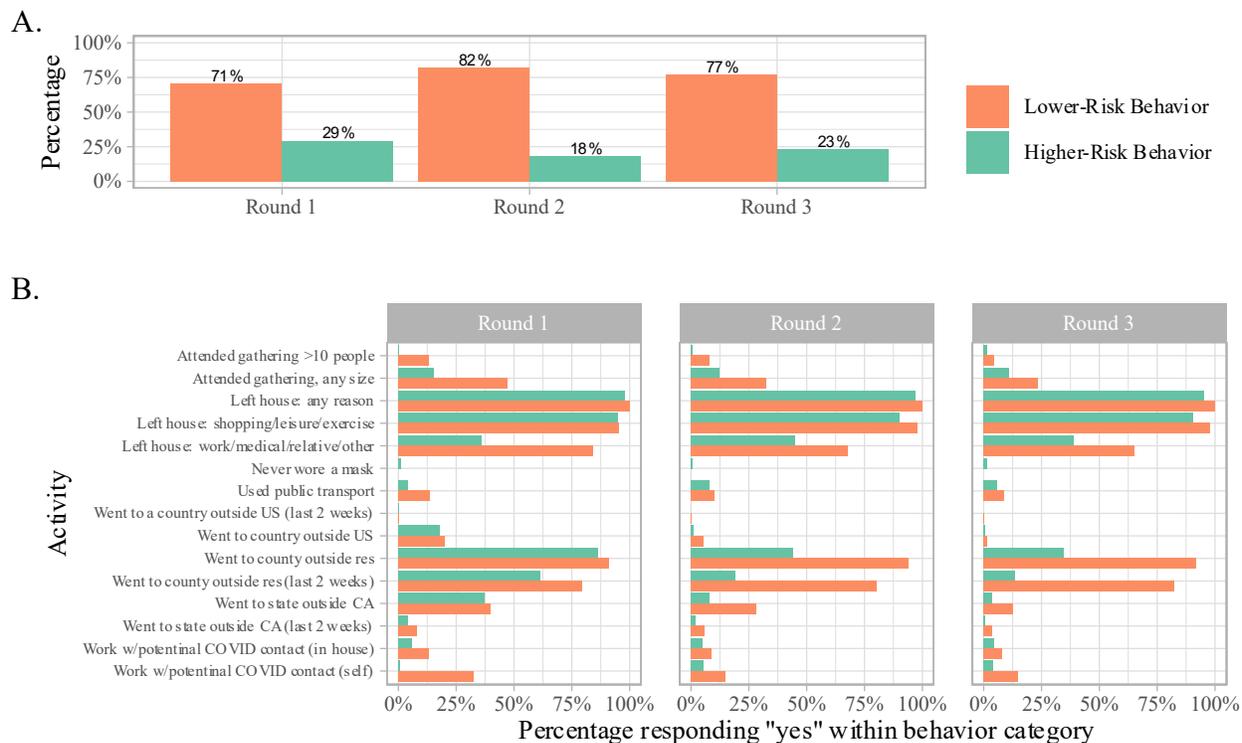

487 to spike (natural infection or vaccination) seroprevalence within strata of race/ethnicity and age.

488 Each point represents a stratum of race/ethnicity and age within a ZIP code, the size of the point

489 is proportional to American Community Survey population size.
