28 **Abstract**

29

30 There has been a growing interest in studying the causes and impact of the Great Chinese  
31 Famine of 1959-61. The Cohort Size Shrinkage Index (CSSI) is the most widely used  
32 measure to examine famine intensity and was used in at least 28 Chinese famine studies  
33 to date. We examined the potential impact of violations of three requirements for a valid  
34 CSSI measure: reliable information on cohort size by year of birth; a stable trend of  
35 cohort size by year of birth; and the absence of significant regional migration. We used  
36 data from the 1% China 2000 Census to examine the trend of cohort size over time and  
37 concentrated on the time window between 1950-70 to exclude policies and events with a  
38 large impact on birth trends other than the famine itself.

39

40 Across China we established a significant difference in cohort size trends between pre-  
41 famine births and post-famine births, violating one of the main requirements for a valid  
42 CSSI measure. This leads to systematic differences in CSSI depending on what non-  
43 famine years are selected for comparison. At the province level, CSSIs estimated based  
44 on pre- & post-famine births tend to overestimate famine intensity at higher exposure  
45 levels and underestimate intensity at lower levels compared to CSSIs based on pre-  
46 famine births alone. This is problematic and demonstrates that the CSSI is not as robust  
47 an estimator of famine intensity as had been assumed previously. We recommend  
48 therefore that all CSSI should be based on pre-famine birth trends.

49

50 Using data from Sichuan province, we demonstrate a less pronounced dose-response  
51 relation between famine intensity and tuberculosis outcomes using pre-famine based  
52 CSSI as compared to reported patterns based on pre- & post-famine based CSSI.  
53 We encourage researchers to re-examine their results of Chinese famine studies as local  
54 differences in cohort size of pre-famine and post-famine births may lead to significant  
55 discrepancies of CSSI estimation and change the interpretation of their findings.

56

57 **Introduction**

58

59 The Great Chinese Famine of 1959-61 (Chinese famine) arose from a combination of  
60 radical agricultural and economic policies and crop failures (1-5). The famine is  
61 associated with over 30 million excess deaths and ranks as one of the largest man-made  
62 disasters (6-9) . The famine varied across regions and over time in China and a variety of  
63 demographic indicators has been used to quantify its intensity because reliable  
64 information on food consumption at the time of the famine is hardly, if ever, available  
65 (10-12).

66

67 Among demographic indicators, the Cohort Size Shrinkage Index (CSSI) is the most  
68 widely used measure of famine intensity, especially in the fields of economics and health  
69 (**Figure 1**). It has been applied to different regions in China to examine potential dose-  
70 response relations between the degree of famine exposure and the number of births,  
71 deaths, and later economic and health outcomes in populations affected by famine (**Table**  
72 **S1**). The CSSI measure compares the observed cohort size of populations born in famine  
73 years to a normally expected cohort size estimated by interpolation or projection (13-16).  
74 A projected cohort size for famine births is usually estimated using the average cohort  
75 size of populations born both before and after the famine (pre- & post-famine births) (14,  
76 17, 18). There is little consistency, however, in the way CSSIs were calculated, with a  
77 wide variety in the selection of data sources, estimating methods, administrative regions,  
78 and the choice of pre-famine, famine, and post-famine years included for study (**Table**  
79 **S1**). As noted, almost all studies combined pre- & post-famine births to construct a  
80 projected cohort size of famine births (**Figure S1**).

81

82 For CSSI to be a valid measure of famine intensity across the country, reliable  
83 information will be needed on some important variables (15, 16): First, the size of  
84 regional birth cohorts, for instance from census data at the province or prefecture level;  
85 second, existing trends of cohort size over time in non-famine periods so that any  
86 deviations from existing trends in famine years can be documented; and third, the  
87 possible impact of regional migrations, if birth cohorts are classified by current residence  
88 rather than place of birth.

89

90 To date, no publications on the Chinese famine have examined in sufficient detail if the  
91 quality of the information to construct a valid CSSI measure has been adequate for their  
92 research. Also, it remains unknown how robust the composite CSSI measure is to  
93 variations in its component parts. These include: First, variations in cohort size measures  
94 from the use of different data sources, including the 1% China census collected in 1982,  
95 1990, and 2000, and the full province level census; second, disruptions in cohort size  
96 trends by events outside the famine period that make interpolations of famine births from  
97 pre- and/or post-famine births problematic; and third, misclassification of place of birth  
98 from the use of current residence in census records (7, 13-15, 17, 18). We will examine  
99 the robustness of CSSI measure to variations in their component parts using nationwide  
100 data.

101

102 At the prefecture level within Sichuan province in China, we will examine the robustness  
103 of the CSSI famine intensity measure in more detail. A recent study in this province  
104 reported a dose-response relationship between early-life famine exposure and adulthood  
105 tuberculosis using CSSIs constructed based on pre- & post-famine births across  
106 prefectures (18). A re-analysis of this study showed that CSSIs estimated from pre-  
107 famine births alone have a different distribution than CSSIs from pre- & post-famine  
108 births combined (19). Using the latter can introduce an unrecognized bias in CSSI  
109 estimates which over-estimates the dose-response relationship between famine intensity  
110 and adult tuberculosis. On further examination, it became clear that the over-estimate was  
111 driven by post-famine cohort sizes that were significantly different from what was to be  
112 expected from pre-famine trends. This demonstrates that CSSIs calculated from  
113 interpolating pre- & post-famine births are sensitive to deviations in the trend of cohort  
114 size. We therefore need to examine the impact of the different calculating characteristics  
115 of CSSI on its mean and distribution and on the robustness of reported results in  
116 empirical studies (20).

117  
118 For our study, we used the 1% China 2000 Census as the principal data source to  
119 compare trends of cohort size for pre-famine births and post-famine births (19, 21). We  
120 constructed CSSIs based on cohorts born in different years (pre-famine, famine, and post-  
121 famine births) and compared CSSIs' distributions at the province and prefecture levels.  
122 We examined the impact of migration on CSSI by comparing place of birth and current  
123 residence because this information at the province level is available in the 1% China 2000  
124 Census but not in other census data. We further examined changes in CSSI by using  
125 different non-famine years (pre-famine years vs pre- & post-famine years) based on the  
126 tuberculosis surveillance study in Sichuan Province (15, 16, 18) and changes in CSSI  
127 from variations in the exact years used to define pre-famine, famine, and post-famine  
128 births, and showed how empirical results may change by using different CSSIs. These  
129 findings together show that because of significant changes in cohort size trends across  
130 China and in Sichuan, the choice of non-famine years is by far the most important  
131 constructing characteristic of CSSIs, influencing both its distribution and the results of  
132 empirical studies.

133

## 134 **Results**

135

### 136 **Observed cohort sizes for births 1900-2000**

137

138 **Figure 2A** shows the cohort size by birth year between 1900 and 2000 at the national  
139 level as documented by the 1% China 2000 Census. For individuals born until the late  
140 1950s, a monotone relation is seen of higher mortality with advancing age. This shows as  
141 the smallest number of survivors among the oldest age groups. For individuals born  
142 thereafter, this relation no longer holds. The trend is interrupted in three periods that  
143 show marked declines in cohort size: for individuals born between 1958-62, 1971-80, and  
144 after 1990. In nearly all provinces, the same pattern is seen (**Figure S2**). Because of these  
145 irregularities, choosing an appropriate time window is essential when examining the  
146 cohort size trend and projecting cohort sizes for famine births.

147

## 148 Cohort size trends for births 1950-70

149

150 **Figure 2B** limits the time window to the period 1950-70, covering the periods used by  
151 the previous Chinese famine studies included in **Figure S1**. This selection of birth years  
152 avoids potential modeling artifacts arising from births between 1971-80 or after 1990 that  
153 showed marked declines in cohort size. **Figure 2B** shows two cohort size trends in this  
154 period, the first based on pre-famine births (1950-57) and the second based on post-  
155 famine births (1963-70). The cohort size trends are different as the first shows an increase  
156 with year of birth and the second does not. In most provinces, the pre-famine based  
157 cohort size trend is also different from the post-famine based trend (**Figure S3**). The  
158 difference in trends remained after excluding births in 1963 when cohort sizes increased  
159 with the end of the Chinese famine.

160

## 161 Cohort size projections for famine births 1959-61 are dependent on the choice of 162 non-famine years

163

164 Cohort size projections for famine births depend on trends estimated from either pre-  
165 famine or post-famine births. Since these trends are different, the resulting trend from  
166 combining pre- & post-famine births as has been done in previous Chinese famine studies  
167 (**Table S1 and Figure S1**) can be different from either of the component trends. As an  
168 illustration at the province level, we compared the observed population cohort size for  
169 famine births of 1959-61 with the projected population sizes using either a) the observed  
170 pre-famine births (1950-57), or b) the observed pre- & post-famine births combined  
171 (1950-57 & 1963-70) (**Table S2**). The projected populations are higher than the observed  
172 populations in almost all provinces. The two methods also show significant differences at  
173 the province level, suggesting that estimates of the impact of the famine will depend on  
174 the choice of non-famine years.

175

## 176 Cohort size shrinkage index (CSSI) is dependent on the choice of non-famine years

177

178 The absolute value and the relative rank of CSSI at the province level also depend on the  
179 choice of non-famine years: pre-famine births (1950-57) vs pre- & post-famine births  
180 (1950-57 & 1963-70) (**Table S3**). The difference in pre-famine based and pre- & post-  
181 famine based CSSIs ranges from -16.2% in Qinghai province to 14.1% in Liaoning  
182 province. It is even more extreme for the five special regions, ranging from -60.6% in  
183 Xinjiang to 39.3% in Shanghai (**Table S4**). **Figures 3A-B** show the spatial distribution of  
184 pre-famine based and pre- & post-famine based CSSIs in China. Pre- & post-famine  
185 based CSSI tend to be higher than pre-famine based CSSI in the Midwest and lower in  
186 the Northeast and Southeast (**Figure 3C**). The difference is not constant across the CSSI  
187 range, and at the middle of the range we see a cross-over between the estimates using  
188 different non-famine years. Pre- & post-famine based CSSI tends to be systematically  
189 larger than pre-famine based CSSI at higher average of both CSSIs and smaller at lower  
190 average of CSSIs (**Figure 3D**). Different choices of non-famine years therefore have  
191 opposite effects on CSSI estimates, depending on the magnitude of CSSI. The CSSI  
192 based on place of birth are highly consistent with CSSI based on place of residence  
193 (**Figure S4 and Table S5**). **Figure S5** shows that the mean values of both CSSIs are

194 similar (37.4 vs 37.7) but that pre-famine based CSSI is spread more narrowly around the  
195 mean than pre- & post-famine based CSSI (with a SD of 9.8 vs 14.5 respectively). Dose-  
196 response relations between famine intensity at the province level and later economic and  
197 health outcomes will therefore appear to be more gradual when using the pre- & post-  
198 famine based CSSI because of its wider range used in modeling.

199

200 Nationwide pre-famine based and pre- & post-famine based CSSIs at the prefecture level  
201 are presented in **Table S6**. CSSIs at the prefecture level are based on place of residence  
202 as place of birth at this level was not available. It is therefore impossible to assess intra-  
203 province migration and its potential impact on CSSI. **Figure S6** shows spatial variations  
204 of residence based CSSIs at the province level and the prefecture level. We show  
205 variations based on pre-famine births (**Figures S6 A and D**), on pre- & post-famine  
206 births (**Figures S6 B and E**) and of their difference (**Figures S6 C and F**). Regardless of  
207 province level CSSI, the maps show residual CSSI variation comparing prefectures in a  
208 single province (**Figures S6 D-F**). This is illustrated numerically by the wide range in  
209 prefecture based CSSIs within individual provinces (**Table S7**).

210

### 211 **Comparisons with the 1% China 1990 Census**

212

213 The 1% China 1990 Census has been widely used in previous studies although place of  
214 birth was missing from this collection (**Table S1**). For comparison, we therefore  
215 compared CSSIs at the province level based on this census to CSSIs based on either place  
216 of residence or place of birth as recorded in the 1% China 2000 Census. For all  
217 comparisons, the findings were highly consistent and inter-correlations exceeded .95  
218 (**Table S5**). A highly similar cross-over between the estimates using different non-famine  
219 birth years can also be observed based on the 1% China 1990 Census (**Figure S7**).

220

### 221 **Applying pre-famine based and pre- & post-famine based CSSIs to the tuberculosis** 222 **surveillance study in Sichuan Province**

223

224 We applied pre-famine based and pre- & post-famine based CSSIs to the tuberculosis  
225 surveillance study in Sichuan Province using the 1% China 2000 Census for Sichuan and  
226 the full Sichuan 2000 Census (18-20). Unlike CSSIs at the province level, pre-famine  
227 based CSSI at the prefecture level within Sichuan Province have a smaller mean and  
228 wider range compared to pre- & post-famine based CSSIs (**Table S8**). Using the 1%  
229 China 2000 Census, the pre-famine based CSSI dose-response estimate (IRR 0.21, 95%  
230 CI: -0.29, 0.71) is less than half the pre- & post-famine based CSSI estimate (IRR 0.52,  
231 95% CI: -0.33, 1.36) (**Figure 4 and Table S9**). Using the full 2000 Sichuan Census (20),  
232 the pre-famine based CSSI dose-response estimate (IRR 0.38, 95% CI: -0.12, 0.88) was  
233 also less than half the pre- & post-famine based CSSI estimate (IRR 0.91, 95% CI: 0.19,  
234 1.62). We estimated the difference of the two estimates 0.55 (95% CI: 0.06, 10.4) from  
235 the bootstrap method. Using different time windows for pre-famine years to construct  
236 CSSIs only leads to a minimal change in dose-response effect estimates (IRR 0.37, 95%  
237 CI: -0.12, 0.86 using 1949-57 as pre-famine years; IRR 0.40, 95% CI: -0.02, 0.82 using  
238 1945-57 as pre-famine years).

239

## 240 **Discussion**

241

242 Over the last three decades, there has been a marked increase in the number of studies of  
243 the Chinese famine, including at least 28 studies that have used CSSI (**Figure 1**).

244 Demographers have examined the famine's impact on mortality, fertility, and the sex  
245 ratio (8, 9, 22-24). Political scientists described social factors related to the famine (1-6).  
246 Economists and medical professionals have compared early-life famine exposure with  
247 later economic achievements and health (10, 15, 18, 25-27). Such studies have improved  
248 our understanding of underlying causes and of long-term impacts of this man-made  
249 disaster. A robust and valid indicator of famine intensity at the local level is needed  
250 however to compare study findings and interpret study results (10, 11, 28). The Cohort  
251 Size Shrinkage Index (CSSI) is the measure that has been the most widely used for this  
252 purpose.

253

254 To construct a valid CSSI, reliable information will be needed on the size of cohorts born  
255 before, during, and after the famine (15, 16). There should also be no disruptions in  
256 overall cohort size trends from non-famine sources (15, 16, 20). And current place of  
257 residence, as collected in the census, should be an adequate indicator of place of birth.  
258 We established that CSSI measures of famine intensity across China were extremely  
259 similar for different sources of birth cohort size, including the 1% China 2000 Census,  
260 the 1% China 1990 Census, and the full Sichuan 2000 Census. CSSI estimates were also  
261 not affected by using place of residence rather than place of birth as both available in 1%  
262 China 2000 Census. And CSSI estimates were robust to small variations in the definition  
263 of pre-famine, famine and post-famine years as seen in published studies.

264

265 Contrariwise, CSSI measures of famine intensity were highly sensitive to the choice of  
266 non-famine years. When selecting pre-famine births, post-famine births, or both groups  
267 combined to project famine births, all selections lead to different estimates of CSSI.  
268 Specifically, combining pre- & post-famine births to construct CSSI leads to different  
269 estimates of famine intensity compared to selecting pre-famine births. This is problematic  
270 and demonstrates that the CSSI is not as robust an estimator of famine intensity as had  
271 been assumed previously (13-16, 18).

272

273 In the following, we discuss in turn our CSSI findings using different sources of cohort  
274 size of pre-famine, famine, and post-famine births; the impact on CSSI of changing  
275 cohort size trends over time; potential misclassification of place of birth from using  
276 census data on current residence; and urban-rural famine differentials.

277

### 278 **Combining sources to determine pre-famine, famine, and post-famine cohort size**

279

280 In Chinese famine studies to date, different waves of the China population census  
281 between 1980 and 2000 have been used to construct CSSIs at multiple administrative  
282 levels (**Table S1**). Available studies suggest that the population census data as collected  
283 in post-famine era, especially in 1990 and 2000, are fit for this purpose (13-16, 18, 29,  
284 30).

285 We cannot think of any reason why the collected information on date of birth and  
286 residence, and additionally on place of birth in the 2000 census, might be systematically  
287 biased. Representation in the 1990 and 2000 census for those still alive at the time will  
288 also be in essence complete and especially is not conditional on place or date of birth. We  
289 therefore used the most recent publicly available data from the 1% China 2000 Census to  
290 collect the needed information for estimating famine intensity (5, 7, 15, 16).

291

292 On the use of the 1% China 2000 Census as our main data source and not the 1% China  
293 1990 Census, we note that our study findings are highly consistent across census years  
294 (**Table S5**). In both census waves, we found the same systematic differences between  
295 pre-famine based CSSI and pre- & post-famine based CSSI (**Figure 3D and Figure S7**).  
296 For our analysis of CSSI at the prefecture level in Sichuan province from different  
297 sources, we note that for the 1% China 2000 Census information was available on year  
298 and month of birth. This could lead to minor differences between findings from the full  
299 Sichuan 2000 Census where year of birth was calculated from the difference between  
300 reported age at the time of the census and the year of census (18, 20).

301

### 302 **Changing cohort size trends and how these affect CSSI estimates**

303

304 We found that major social and political events can have a big impact on the trend of  
305 cohort size. Most importantly, the famine itself is likely to have affected subsequent  
306 cohort trends for births and deaths (7-9). As another example, family planning pilot  
307 programs introduced in some regions from the 1960s and nationwide in the 1970s most  
308 likely contributed to the cohort size decline observed for individuals born after these  
309 years (22, 31, 32). For Chinese famine studies, it is critically important therefore to select  
310 a suitable time window for observation of a stable cohort size trend that can be used to  
311 project famine related changes. We think this is only possible with a focus on pre-famine  
312 births as further explained below.

313

314 Chinese famine studies to date (**Table S1**) have failed to recognize that the cohort size  
315 trends among pre-famine births and post-famine births differ substantially (**Figure 2B**  
316 **and Figure S3**). This difference can be illustrated by comparing the observed and the  
317 projected cohort size for famine births based on either pre-famine births or the commonly  
318 used pre- & post-famine births (**Table S2**). The trend change also leads to different CSSI  
319 estimates. Unfortunately, there is no constant difference in CSSI estimates over the CSSI  
320 range as the measures intersect: pre- & post-famine based CSSIs tend to be  
321 systematically larger than pre-famine based CSSIs at higher mean CSSIs and  
322 systematically lower at lower mean CSSIs (**Figure 3D**). In our view, this shows a  
323 systematic bias of the commonly used CSSI based on pre- & post-famine births.

324

325 Previous Chinese famine studies have ignored the change in cohort size trend and have  
326 used the average cohort size of pre- & post-famine births to generate CSSIs (**Table S1**  
327 **and Figure S1**). To avoid the problems identified above with changing trends, we  
328 projected cohort sizes for famine births by extrapolating the trend of pre-famine births in  
329 1950-57. This approach was also used in the earliest demographic study of excess  
330 mortality associated with the Chinese famine (8) and the Ukraine famine of 1932-33 (33).

331

### 332 **Changing trends can also affect CSSI distributions**

333

334 In many current Chinese famine studies (**Table S1**), CSSI has been incorporated in  
335 regression models as a continuous measure of famine intensity. Changing cohort size  
336 trends of pre-famine births and post-famine births may not only affect CSSI point  
337 estimates but also their distributions. This changes how the study results will be  
338 interpreted.

339

340 Using data from the tuberculosis surveillance study in Sichuan Province (15, 16, 18), we  
341 demonstrated that the dose-response relation between CSSI and the IRR for tuberculosis  
342 is much weaker using pre-famine births as the reference compared to using the combined  
343 pre- & post-famine births as the reference (**Figure 4**). This holds true both when using  
344 data from the 1% China 2000 Census and the full Sichuan 2000 Census. Our findings  
345 illustrate how the choice of non-famine years determines the nature of a possible dose-  
346 response relationship.

347

### 348 **Misclassification of place of birth**

349

350 At the province level, the 1% China 2000 Census includes information on place of birth.  
351 We found that CSSI constructed based on place of birth is highly comparable to CSSI  
352 based on place of residence (**Figure S4**). This is consistent with our finding that inter-  
353 province migration among births 1950-70 was as low as 6%. At the province level, place  
354 of residence in 1990 or 2000 was a sufficient indicator of place of birth for the purposes  
355 of our study. At the prefecture level, information on place of birth was not available.  
356 Therefore, the degree of intra-province migration is unknown and also its potential to bias  
357 studies that rely on place of residence as a proxy for place of birth.

358

359 Large intra-province migrations from rural to urban areas in specific regions are likely  
360 among the 1950-70 birth cohorts: initially from rapid industrialization which led to a  
361 large-scale transfer of labor from agriculture to industry and from rural to urban locations  
362 in 1957-60 (34); then possibly in reverse following production declines and the Chinese  
363 government decision to send workers back to their rural homes in 1961 to help increase  
364 food production (3); then again from rural to urban with the development of the urban  
365 economy (35). These migrations may have been mitigated to some extent however by a  
366 variety of government policies that were designed to control migration (36-39). For  
367 famine studies at the prefecture level, collecting additional information on migration over  
368 the life-course will therefore be important.

369

### 370 **Urban-rural famine differentials**

371

372 There was a substantial rural-urban difference in famine intensity because government  
373 policies prioritized food security in urban areas (7-9). As an example, urban population  
374 deaths increased from 9.2 to 13.8 per thousand between 1958-60, showing an increase of  
375 close to 50% (40). By contrast, rural population deaths increased from 12.5 to 28.6 per  
376 thousand, showing an increase of well over 100% (40). The provincial famine intensity

377 was mainly determined by the situation in rural areas because over 80 percent of Chinese  
378 population at the time lived in rural areas (8, 41). When we excluded urban populations  
379 from our analyses of the 1% China 2000 Census, we found our results did not change.

380

### 381 **Strengths and Limitations**

382

383 Our study has many strengths. We used census data to construct robust measures of  
384 famine intensity; demonstrated that combining pre- & post-famine births to construct  
385 CSSI can lead to unrecognized bias in estimating famine intensity and can exaggerate  
386 potential dose-response relations as empirically demonstrated by the tuberculosis study;  
387 and avoided misclassification of place of birth at the province level. These strengths  
388 provide the basis for our recommendations for the analysis of famine studies in China.

389

390 There are also some potential limitations. Census data only include individuals who live  
391 long enough to be included and this could be a problem if the famine had a long-term  
392 effect on mortality. In the one study we know on the question, this does not seem to be  
393 the case (38). We also established in simulations that the CSSI as a measure of famine  
394 intensity is highly robust to potential changes in mortality among famine births. And  
395 potential misclassifications of place of birth could arise if pregnant women migrated  
396 during the famine and gave birth in another provinces. By regulation, a child's place of  
397 birth was registered however according to mother's Hukou status (42).

398

### 399 **Suggestions for future studies**

400

401 While we advocate the use of CSSI in Chinese famine studies, results should be  
402 presented with their limitations in mind. Because of different pre-famine and post-famine  
403 cohort size trends, the use of pre-famine based CSSI will generally be the most  
404 appropriate. Current high-quality studies should therefore be re-analyzed with this in  
405 mind and divergent findings compared and discussed (14-16, 18, 43, 44).

406

407 For the use in future studies, we provide data of CSSI at both the province and prefecture  
408 level in supplementary materials (**Table S6**). This information is essential to identify  
409 provinces and prefectures across China where famine intensity was highest. These will be  
410 the most suitable locations for future famine studies. We suggest that the focus should  
411 first be on studies in one or two of the most famine-severe provinces, including Sichuan  
412 and Anhui provinces (**Figure S6 & Table S7**). Prefecture based studies should be  
413 attempted later, as there can still be substantial variations in famine intensity within  
414 province. These studies will generate improved estimates of famine intensity at the local  
415 level as will be needed to establish potential dose-response relationships between famine  
416 exposure and its long-term impact.

417

### 418 **Conclusions**

419

420 Chinese famine studies to date have failed to recognize that cohort size trends among pre-  
421 famine births and post-famine births can differ substantially. This is problematic as the  
422 construction of CSSI as a valid measure of famine severity relies on a stable cohort size

423 trend. We demonstrate that CSSI is not a robust estimator of famine intensity as had been  
424 assumed previously. It can overestimate famine intensity at higher exposure levels and  
425 underestimate intensity at lower levels. As an alternative for Chinese famine studies, we  
426 recommend CSSI based on pre-famine births alone.

427

## 428 **Materials and Methods**

429

### 430 **Main Data**

431

432 Previous Chinese famine studies have used population census data collected from the  
433 1980s onwards to construct cohort size shrinkage indexes (CSSIs) for selected regions at  
434 different administrative levels (**Table S1**). Our study used the 1% China 2000 Census  
435 (<https://international.ipums.org/international/>) (21), because it provides more detailed  
436 demographic information compared to other census data. Relevant to our analyses, this  
437 sample includes birth year, place of birth at the province level, and place of residence at  
438 both the prefecture and province levels (30). By contrast, the 1% sample of China's 1990  
439 census does not provide information on place of birth. In the 1% China 2000 Census we  
440 can therefore compare place of birth at the time of the famine with place of residence at  
441 the 2000 censuses for individuals who were then still alive. This comparison provides  
442 information on inter-province migrations over time.

443

444 We examined the cohort size of selected populations by year of birth. In selecting the  
445 time window of 1950-1970, we aimed to define a relatively stable period in terms of birth  
446 trends that was only interrupted by the famine events. The beginning of the period  
447 corresponds to the establishment date of the People's Republic of China in 1949 and the  
448 end by the introduction of family planning policies across China in the 1970s. Our  
449 nationwide study included the 29 province level regions and 340 prefectures. The regions  
450 are: Sichuan (SC), Anhui (AH), Guizhou (GZ), Hunan (HuN), Henan (HeN), Qinghai  
451 (QH), Jiangsu (JS), Ningxia (NX), Guangxi (GX), Gansu (GS), Shandong (SD), Yunan  
452 (YN), Hubei (HuB), Fujian (FJ), Hebei (HeB), Zhejiang (ZJ), Jiangxi (JX), Guangdong  
453 (GD), Liaoning (LN), Shanxi (SX), Shaanxi (SaX), Jilin (JL), Inner Mongolia (IM),  
454 Heilongjiang (HLJ), Beijing (BJ), Tianjin (TJ), Shanghai (SH), Xinjiang (XJ), and Tibet  
455 (TB). Before the 1980s, Hainan was part of Guangdong province, and Chongqing (CQ)  
456 was part of Sichuan province. Five province level regions were grouped separately. These  
457 included the 3 municipality cities, Beijing, Tianjin and Shanghai which received  
458 preferential food supplies during the famine and where early family planning policies  
459 were introduced starting in the 1960s (45), and two less famine-affected provinces,  
460 Xinjiang and Tibet, to which government policies encouraged active immigration (46).

461

### 462 **CSSI construction from expected cohort size in the absence of famine**

463

464 Previous Chinese famine studies have generally calculated CSSI as  $\frac{N_{\text{non-famine}} - N_{\text{famine}}}{N_{\text{non-famine}}}$   
465 for regions at different administrative levels, where  $N_{\text{famine}}$  is the observed average  
466 cohort size of famine births and  $N_{\text{non-famine}}$  is the average cohort size of the combined  
467 pre- & post-famine births. This assumes that the average cohort size of pre- & post-  
468 famine births represents the expected cohort size in the absence of famine. We have

469 suggested however that using the average cohort size of pre- & post-famine births may  
470 introduce bias in constructing a CSSI because the cohort size of post-famine births shows  
471 irregular patterns (19). In addition, taking averages alone may overlook underlying trends  
472 of cohort size (20).

473

474 To address these concerns, we compared linear extrapolations of populations born in  
475 different non-famine years (pre-famine births vs pre- & post-famine births) to project  
476 expected cohort sizes at the province level in the absence of famine. Linear models were  
477 used as these appeared to correspond adequately with the monotone increase in cohort  
478 size in the births years 1950-1957 preceding the famine. More refined including  
479 exponential models with quadratic terms showed no significant improvement in fit.

480

481 We defined the birth years 1959-61 as famine years, 1950-57 as pre-famine years, and  
482 1963-70 as post-famine years. We excluded births in 1958 or 1962 from analysis because  
483 the beginning and the end of the Chinese famine differed by province and births in these  
484 years could easily be misclassified on exposure status. Two sets of CSSI were  
485 constructed: the first based on linear extrapolation of pre-famine births (1950-57) and the  
486 second on the interpolation of pre- & post-famine births (1950-57 & 1963-70). The  
487 distributions of the two CSSI sets were compared. In all tables and figures, provinces  
488 were ordered by the average CSSI from the two sets. Spatial variations of the two sets of  
489 CSSI were mapped at both the province and prefecture levels. Results based on the 1%  
490 China 2000 population census were compared with findings based on the 1% China 1990  
491 population census.

492

### 493 **Applying CSSIs to tuberculosis surveillance study in the Sichuan province**

494

495 The tuberculosis surveillance study in the Sichuan province collected information on  
496 clinically diagnosed and laboratory-confirmed active tuberculosis cases diagnosed  
497 between 2005 and 2018 classified by sex, age at diagnosis, year of diagnosis, and  
498 residential prefecture (47). Following previous analytic approaches, a mixed-effects  
499 meta-regression was run to evaluate associations between the famine intensity and  
500 tuberculosis risk in famine cohort (born in 1958-62) at the prefecture level in Sichuan  
501 province (18-20). For famine births, we fitted linear models to examine the relation  
502 between famine intensity as represented by CSSI on the log of the ratio of the observed  
503 vs expected non-famine incidence rates. We modeled multiple sets of CSSI using a)  
504 different combinations of non-famine years (pre-famine years vs pre- & post-famine  
505 years) at prefecture level in Sichuan province and b) either the 1% China 2000 Census for  
506 Sichuan province or the Full Sichuan 2000 Census. The data and code used for our study  
507 are publicly available at Github repository [https://github.com/qu-cheng/TB\\_famine](https://github.com/qu-cheng/TB_famine).  
508 Detailed analytical methods can be found elsewhere (18).

509

### 510 **Data Availability**

511

512 All data and code necessary to reproduce the main findings of this study are available at  
513 the Github repository: [https://github.com/chunyu-yes/CSSI\\_famine\\_severity](https://github.com/chunyu-yes/CSSI_famine_severity).

514

515 **Acknowledgments**

516

517 The authors are particularly grateful to the Minnesota Population Center for providing the  
518 data of the 1% China 1990 and 2000 Census, the National Bureau of Statistics in China  
519 for originally producing the census data, and the research team at Berkely University for  
520 making the data of tuberculosis surveillance study in the Sichuan province publicly  
521 available.

**Figure 1. Chinese famine studies using cohort size shrinkage index (CSSI)**  
 Detailed information of listed studies is available in Table S1.

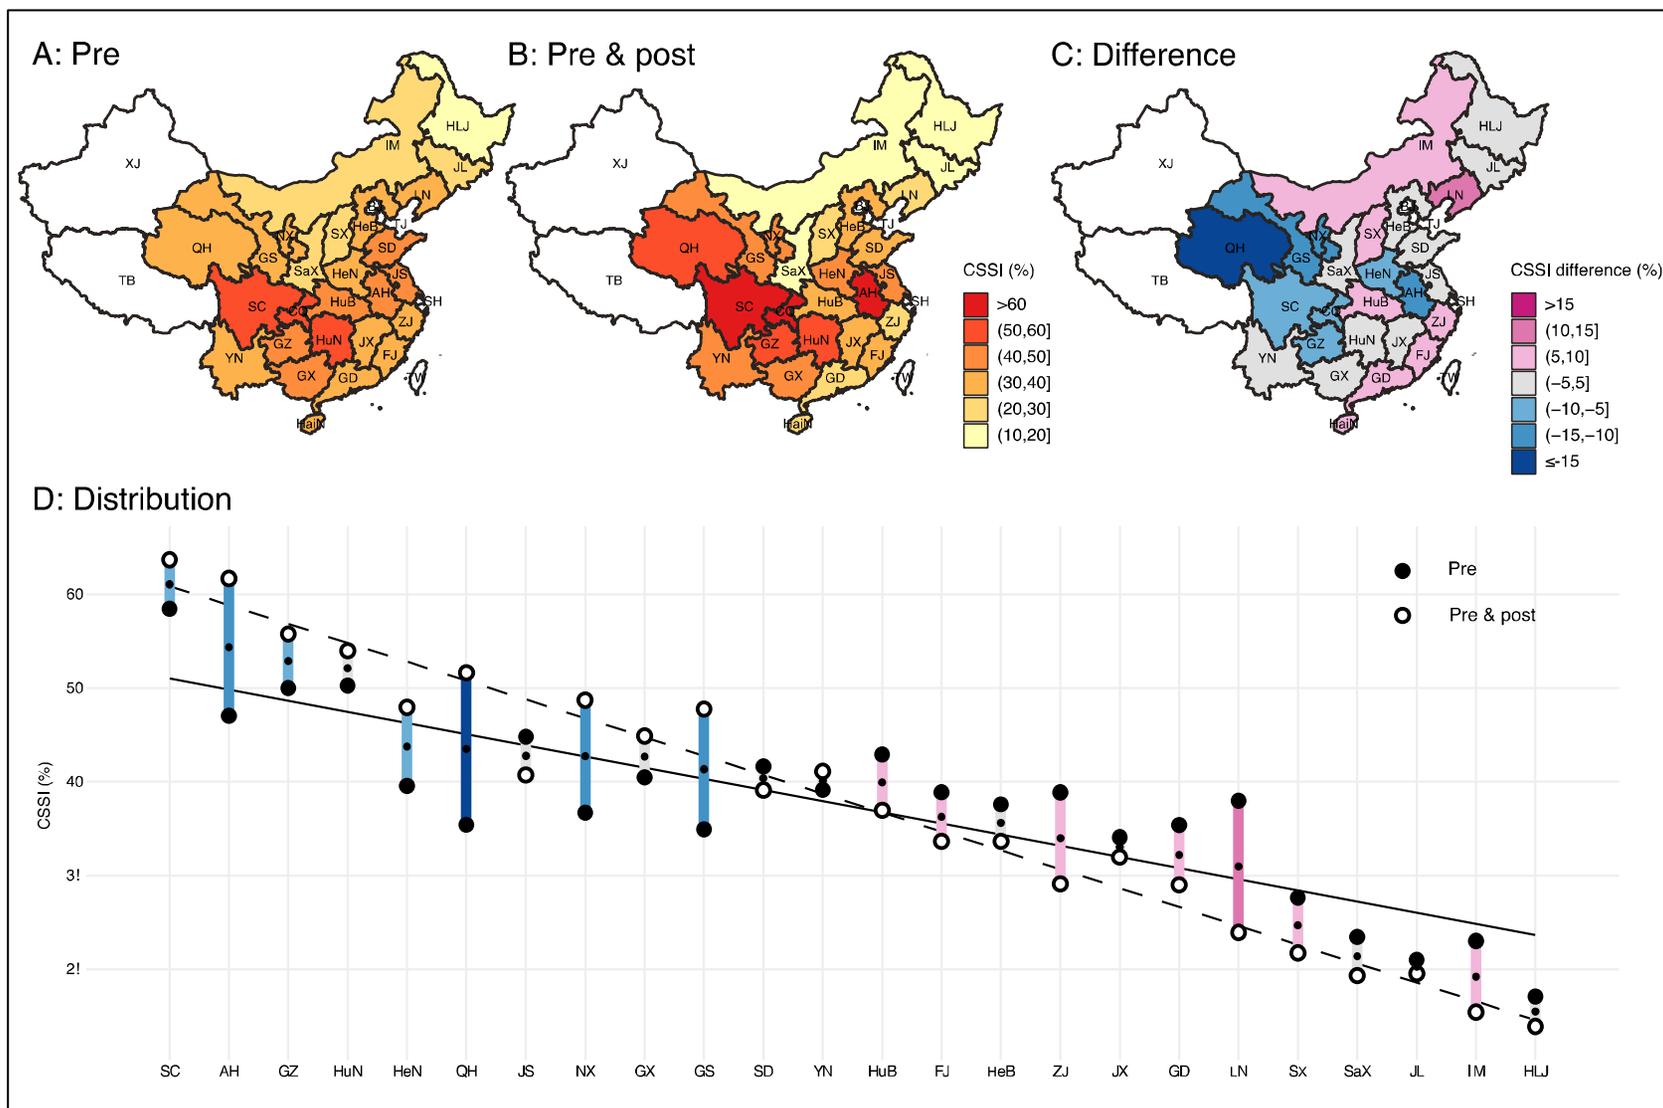

**Figure 2. Cohort size by birth year in China.**

A. Cohort size by birth year, 1990-2000.

B. Cohort size trend from linear regression either based on either pre-famine births (1950-1957) or post-famine births (1963-1970).

Data: 1% China 2000 Census, place of birth.

**Figure 3. Pre-famine based cohort size shrinkage indexes (CSSI), pre- & post-famine based CSSI, and their difference at the province level**

A. Provincial CSSI (%) based on pre-famine births in 1950-57.

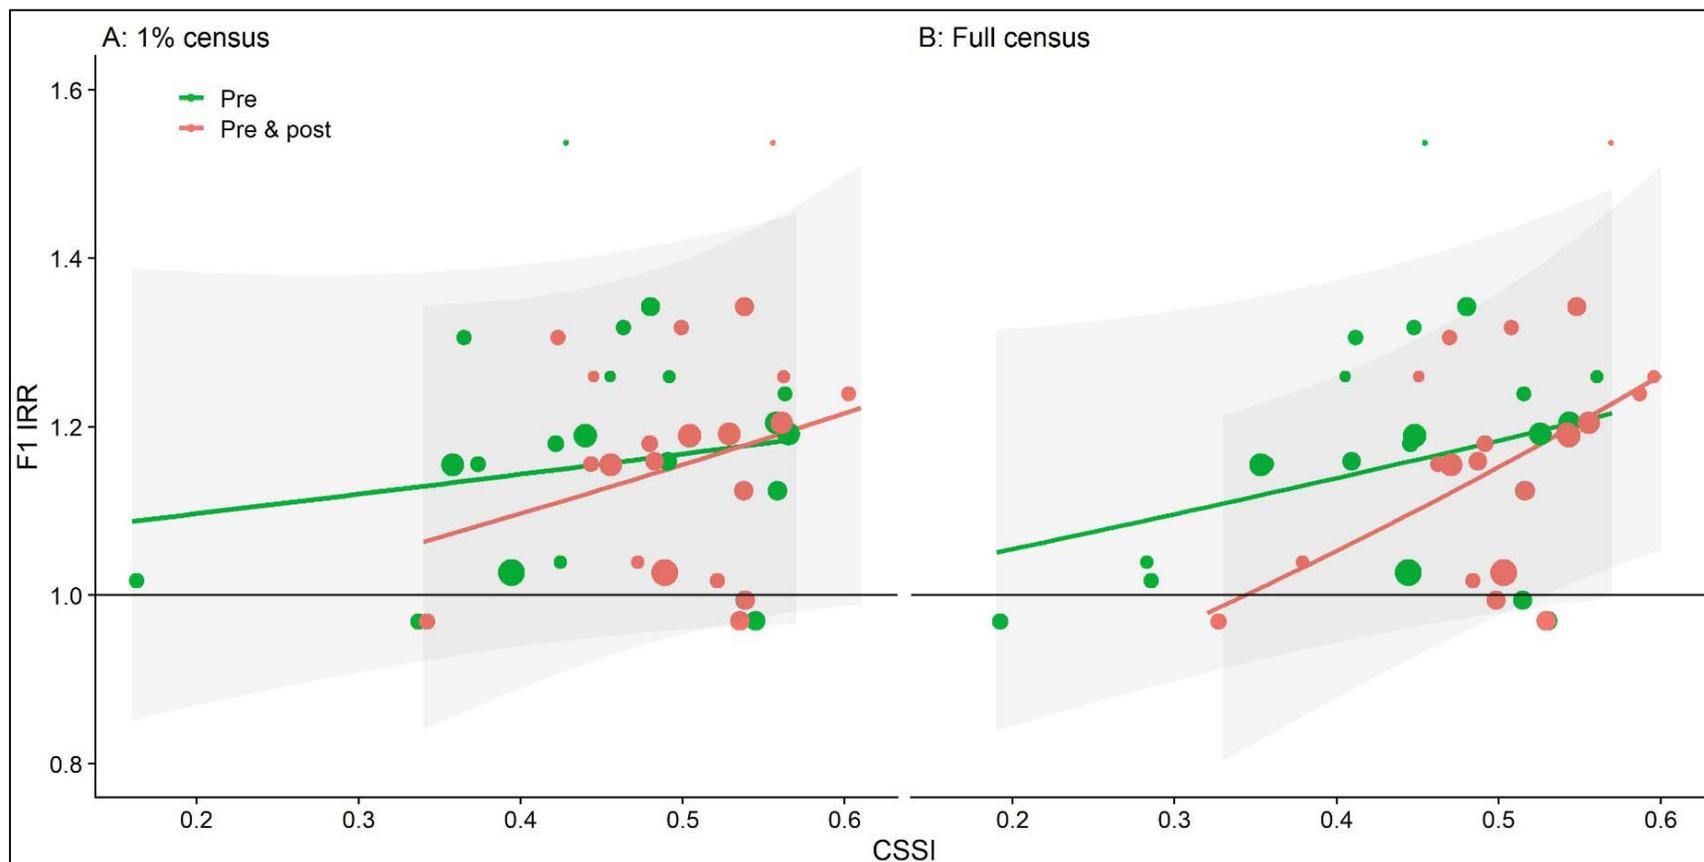

B. Provincial CSSI (%) based on pre- & post-famine births in 1950-57 & 1963-70.

C. Difference of provincial CSSI (%) between panel A and panel B.

D. Provinces are ordered by the average of pre-famine based and pre- & post-famine based CSSIs. The solid line represents the linear regression of pre-famine based CSSI (filled circles) over the average of the two CSSIs. The dash line represents the linear regression of pre- & post-famine based CSSI (unfilled circles) over the average of two CSSIs. Each bar represents the difference of pre-famine based and pre- & post-famine based CSSIs for each province, and its color coding follows the panel C.

Full names corresponding to province abbreviations can be found in 'Materials and Methods' section.

Data: 1% China 2000 Census, place of birth.

**Figure 4. Scatterplot of CSSI and incidence rate ratio (IRR) of tuberculosis among F1 across prefectures in Sichuan province**

Each prefecture is represented by a dot. The size of the dot is proportional to the inverse variance of the estimated IRR of each prefecture. The lines represent the meta-regression fits, and the shaded areas represent the 95% CIs.

A. Data: 1% China 2000 Census, Sichuan Province, year of birth and place of residence.

B. Data: Full Sichuan 2000 Census, age at the time of the census and place of residence.
