## Abstract

Emerging SARS-CoV-2 variants of concern/interest (VOC/VOI) raise questions about effectiveness of neutralizing antibodies derived from infection or vaccination. Here, we have assessed a total of 104 blood specimens, consisting of convalescent samples after infection with early-pandemic SARS-CoV-2 (pre-VOC) or with Alpha, Beta, Gamma or Delta, post-vaccination samples after double-dose mRNA-vaccination as well as samples after vaccine break-through infections with Delta or Omicron. Neutralization against seven authentic SARS-CoV-2 isolates (B.1, Alpha, Beta, Gamma, Delta, Zeta, Omicron) was assessed by plaque-reduction neutralization assay.

We found highest neutralization titers against the homologous (previously infecting) variant, with lower neutralization efficiency against heterologous variants. Loss of neutralization against heterologous variants showed considerably variability between convalescent groups suggesting that a variant-specific infection background influences immune escape characteristics.

Convalescent samples from pre-VOC SARS-CoV-2, Alpha, Beta, Gamma and Delta-infected individuals all showed a significant loss of neutralization for Omicron but to a varying degree (23.0-fold in Beta-convalescent up to 56.1-fold in Alpha-convalescent samples), suggesting that infection-derived immunity, independent of the infecting variant is most likely only poorly protective against Omicron. Of note, former variant of concern Zeta showed also a pronounced escape form neutralization of up to 28.2-fold in Alpha convalescent samples.

Two-dose vaccinated individuals showed robust neutralization against B.1 and only slightly lower neutralization titers for Alpha, Beta, Gamma, Delta and Zeta, with fold-change reduction for heterologous virus between 2.8 (for Alpha) to 6.9 (for Beta). In contrast to convalescent specimens, escape from neutralization for Zeta was largely restored in vaccinated individuals, while Omicron showed a strongly reduced neutralization of 85.7-fold compared to pre-VOC SARS-CoV-2.

Robust neutralization titers were observed in double-vaccinated individuals with subsequent Delta break-through infections, that also neutralized Omicron with a loss of only 12.5-fold. Individuals with an Omicron breakthrough infection showed high neutralization titers for both Delta and Omicron, with only a 1.5-fold loss for Delta neutralization. This suggests that infection with antigenically different variants can boost immunity against variants that are antigenically similar to the vaccine strain.

We conclude that for the assessment of escape from neutralization by new VOCs such as

Omicron, the complexity of background immunity due to individual and regional differences

needs to be taken into account. Geographic variation in the proportion of individual with

infection- or vaccination-derived immunity or a combination of both could have substantial

influence on the course of the pandemic. Combined infection/vaccination immunity after

break-through infections could ultimately lead to broad immunity also against non-homologous

variants.

## Introduction

In late 2019, the Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) emerged in Wuhan (China) causing a pandemic that led to an unprecedented international health crisis of yet unknown outcome [1, 2]. Shortly after its emergence, SARS-CoV-2 acquired the D614G mutation in the spike protein in February 2020, which quickly replaced all other circulating variants and spread worldwide. The evolutionary advantage of D614G is associated with enhanced binding to the human receptor and increased replication and thus presumably better transmissibility [3]. After largely uncontrolled transmission on a global scale during 2020, the emergence of the first variants of concern (VOCs) was observed [4]. The VOCs consist of the Alpha variant, first detected in the UK; the Beta variant, first detected in South Africa, the Gamma variant, first detected in South America, the Delta variant, first detected in India and the Omicron variant, very recently reported from South Africa [5]. Variants of concern were characterized by a rapid increase in case numbers and they quickly outcompeted earlier strains in their region of emergence. The latest emergence is the Omicron variant in late 2021 with the so far highest number of mutations compared to earlier variants and the majority of them located in the spike protein [4]. Thus, suspicion of escape from antibody responses derived from earlier variants and vaccines by Omicron is high.

In addition to VOCs, other variants were identified that were of less concern and therefore classified as variants of interest (VOI) due to aspects in their epidemiology or genetic signatures potentially leading to an altered phenotype, among them the (former) VOI Zeta that arose in parallel with the Gamma variant in South America at a time when a local surge in cases was observed but has disappeared in the meanwhile [6-10].

Currently, few treatments are widely available for SARS-CoV-2 and mostly dedicated to risk groups, therefore prevention and protection through vaccine-mediated immunity is still the proposed method for ending the pandemic [11]. Depending on countries, medium to high levels of population immunity have already been reached through vaccination or infection, but there are huge geographical differences when it comes to the proportions of the population infected, different circulation of variants against which immunity was obtained, percentage of vaccinated individuals, vaccine doses and type of vaccine used.

In light of that, it is of particular importance to evaluate the neutralizing potential of elicited antibodies against clinical isolates of VOCs/VOIs to detect immune escape variants early and understand the impact of such variants on the further course of the pandemic.

The mRNA-based vaccine Pfizer-BioNTech BNT162b2 encodes a stabilized full-length SARS-CoV-2 spike ectodomain derived from the Wuhan-Hu-1 genetic sequence and elicits

potent neutralizing antibodies [12], as does the mRNA-based vaccine Moderna mRNA-1273,
encoding a stabilized prefusion SARS-CoV-2 spike protein [13]. However, emerging SARS-
CoV-2 variants include multiple substitutions and deletions in the major target of neutralizing
antibodies, the spike glycoprotein, including the N-terminal (NTD) and the receptor-binding
domains (RBD), with the largest number of mutations of over 30 observed in the Omicron
variant. This raises the question of whether neutralizing antibodies induced by early circulating
strains or by current vaccines can effectively neutralize recently emerged virus variants. So far,
studies indicated that mutations that have been accumulating in the spike protein, especially in
the RBD, are associated with increased affinity to the human ACE2 receptor [14], as well as
with resistance to neutralization from antibodies of previously infected or vaccinated patients
[15]. Mutations in the RBD pose the greatest risk for making SARS-CoV-2 more infectious
and able to escape antibody neutralization [14]. Virus neutralizing antibody have been shown
to be a correlate of protection from SARS-CoV-2 but more insights on neutralizing responses
against emerging virus variants are needed [16-19].

In this study, we investigated the neutralizing potency of a panel of authentic sera or plasma
from individuals vaccinated twice with either BNT162b2 or mRNA-1273, and convalescent
patients that had mild coronavirus disease 2019 (COVID-19). Patients were infected at
different time points during the pandemic with either an early-pandemic (pre-VOC) SARS-
CoV-2 or one of the VOCs Alpha, Beta, Gamma, Delta or Omicron. We used authentic clinical
isolates for pre-VOC SARS-CoV-2 (Pangolin lineage B.1), Alpha, Beta, Gamma, Delta, Zeta
and Omicron which were all isolated from patient samples collected from our routine
diagnostic laboratory. We assessed the neutralizing potential against homologous and
heterologous variants by live virus plaque reduction neutralization test (PRNT), widely
regarded as the gold standard for the detection of SARS-CoV-2-specific neutralizing antibodies
[20].

**Materials and Methods**

**Setting**

The laboratory of virology of the University Hospital of Geneva is participating and
coordinating the SARS-CoV-2 variant and genomic surveillance funded by the Swiss Federal
Office of Public Health with constantly ongoing full genome sequencing of SARS-CoV-2
positive patient samples obtained through the diagnostic unit of our Centre [21]. Up to around
400 positive patient specimens with a cycle threshold (Ct) < 32 are sequenced each week since

march 2021. From each variant that falls into any of the categories of variant of
concern/interest, at least one virus isolate is generated.

**Patient samples**

Convalescent sera or plasma during the early pandemic period (pre-VOC) were collected in the
context of two prospective cohort studies at the Geneva University Hospitals (HUG) and the
Geneva Centre for Emerging Viral Diseases (Understanding COVID study; ethics approval
number: CCER 2020-00516, Persistence study: ethics approval number: CCER 2020-00516).
In addition, anonymized left-over samples from apheresis collection of plasma (all collected in
2020) were available under the general informed consent of the University Hospitals of
Geneva.

Convalescent sera obtained from patients infected with a SARS-CoV-2 variant of concern
(Alpha, Beta, Gamma, Delta, Omicron) were collected in 2021 by contacting patients with
confirmed SARS-CoV-2 infection for a blood collection in the convalescent period for the
purpose of this study, same for vaccine-break through infections (Ethics approval number:
CCER 2020-02323). For each patient infected with a variant, information on the infecting virus
was available by full-genome sequence. No sequence information on the infecting strain was
available from patients infected in 2020, however the first SARS-CoV-2 variant in Switzerland
(Alpha) was only observed on Dec 24, 2020, and all pre-VOC samples were collected before
that date, thus they are considered pre-VOC. Plasma samples from vaccinated healthy
individuals, vaccinated with 2 doses of BNT162b2 (Pfizer/BioNTech) or mRNA-1273
(Moderna) vaccine at 28 days interval were available from a prospective observational study,
collected 30 days after the 2$^{nd}$ dose (Ethics approval number: CCER ICOVax 2021-00430).

Convalescent samples were only collected from individuals with RT-PCR-confirmed diagnosis
of SARS-CoV-2 in our diagnostic unit, and sera/plasma were collected 3-137 days after
diagnosis or symptom onset (days post diagnosis, DPP). All vaccinated individuals were in
addition tested for the presence of nucleocapsid antibodies (Elecsys® Anti-SARS-CoV-2 anti-
N) to screen for unrecognized infection prior to vaccination. There are no differences to be
expected in the PRNT regarding the use of plasma or serum, therefore both sample types are
used in parallel and termed "convalescent samples" throughout the manuscript.

**Viruses and cells.**

181 Vero-E6 and Vero E6-TMPRSS cells were cultured in complete DMEM GlutaMax I medium
182 supplemented with 10% fetal bovine serum, 1x Non-essential Amino Acids, and 1% antibiotics

(Penicillin/Streptomycin) (all reagents from Gibco, USA). Vero-TMPRSS were kindly received from National Institute for Biological Standards and Controls (NIBSC, Cat. Nr. 100978).

All SARS-CoV-2 viruses used in this study were isolated from residual nasopharyngeal swabs collected from patients presenting at the Geneva University Hospitals under general informed consent of the hospital that allows usage of anonymized left-over materials. The following viruses were isolated as follows: B.1, Alpha, Gamma and Zeta were isolated and propagated on Vero E6. The Beta variant isolate was obtained as described previously [22]. Briefly, no primary Beta isolate could be obtained on VeroE6 but only on A549 cells overexpressing human ACE2 [23]. Therefore, after primary isolation, A549-hACE2 cells were mixed with VeroE6 in a 1:1 ratio and inoculated with the passage 1 isolate. The next passage was done on VeroE6 to generate the virus stock. The Omicron variant was primarily isolated on Vero-TMPRSS cells, then transferred to Vero E6 for generation of a virus stock. All virus stocks were titrated on Vero-E6 cells and full genome sequenced. Sequences of initial patient specimens and virus isolates obtained were compared for acquired mutations (**Table S1**). Experiments with live infectious SARS-CoV-2 followed the approved standard operating procedures of our biosafety level 3 facility (BSL-3).

**Plaque Reduction Neutralization Test (PRNT).**

Following the PRNT procedure, Vero-E6 cells were seeded at a density of $4x10^5$ cells/mL in 24-well cell culture plates. A total of 34, 12, 8, 10 and 22 sera/plasma samples from patients infected with pre-VOC SARS-CoV-2, Alpha, Beta Gamma, Delta or sera from individuals vaccinated with BNT162b2/mRNA-1273, respectively, were used for determining the neutralizing titers against B.1 (first pandemic wave strain containing only the D614G substitution in the spike gene), Alpha, Beta, Gamma, Zeta, Delta and Omicron variants as described earlier [24]. Briefly, all sera/plasma were heat-inactivated at 56°C for 30 min and serially diluted in Opti-Pro serum-free medium starting from 1:10 until up to 1:5120 if necessary. Sera/plasma were mixed with 50PFU of variant isolates (B.1, Alpha, Beta, Gamma, Delta, Zeta and Omicron) and incubated at 37°C for 1h. All samples were run in duplicate and for each neutralization experiment an infection control (no serum/plasma) and a reference serum were used to ensure reproducibility between different experiments. Vero-E6 cells were washed 1x with PBS and inoculated with the virus serum/plasma mixture for 1h. Afterwards, the inoculum was removed and 500uL of the overlay medium also used for the plaque assays was added. After incubation for 3 days at 37°C, 5% CO2, the overlay medium was removed,

cells were fixed in 6% formaldehyde solution for at least 1h, plates were washed 1x with PBS

and stained with crystal violet. Plaques were counted in wells inoculated with virus-

serum/plasma mixtures and compared to plaque counts in infection control wells. The 90%

reduction endpoint titers (PRNT$_{90}$) were calculated by fitting a 4-parameter logistics curve with

variable slope to the plaque counts of each serum/plasma using GraphPad Prism version 9.2.0.

For samples that did not reach 90% reduction at a 1:10 dilution, we extrapolated the titer until

a dilution of 1, i.e. undiluted sample. If the extrapolation reached a titer below 1, the sample

was given a value of 0.5 and considered negative.

**Results**

To evaluate the neutralization capacity of SARS-CoV-2 specific antibodies against SARS-

CoV-2 variants (pre-VOC, Alpha, Beta, Gamma, Delta, Zeta and Omicron), a panel of

convalescent blood specimens were used from i) individuals previously infected with pre-VOC

SARS-CoV-2 (n=34), ii) individuals previously infected with VOCs Alpha (n=12), Beta (n=8),

Gamma (n=10), Delta (n=10) iii) BNT162b2 or mRNA-1273 vaccinated individuals with (n=6)

and without prior infection (n=16) iv) BNT162b2 or mRNA-1273 vaccinated individuals with

a break-through infection with either Delta (n=4) or Omicron (n=4) variant (**Table 1**).

*Neutralizing capacity from infection-derived convalescent samples*

Geometric mean PRNT$_{90}$ titers of convalescent specimens from individuals infected with pre-

VOC SARS-CoV-2 were 37.3 (95%CI: 25.4-54.9) against B.1, 16.7 (95%CI: 9.7-28.8) against

Alpha, 14.0 (95%CI: 8.8-22.3) against Beta, 10.3 (95%CI:6.4-16.6) against Gamma, 12.0

(95%CI:7.0-20.3) against Delta, 1.4 (95%CI: 0.9-2.4) against Zeta, and 0.8 (95%CI:0.6-1.2)

against Omicron. Compared to B.1 this results in a fold-change reduction of 2.2 for Alpha, 2.7

for Beta, 3.6 for Gamma, 3.1 for Delta, 25.9 for Zeta and 45.6 for Omicron (**Figure 1A**). None

of the samples failed to neutralize the homologous virus. Only 1/34 (3%), 2/34 (6%), 3/34 (9%)

and 3/34 (9%) failed to neutralize Alpha, Beta, Gamma and Delta, respectively, whereas 21/34

(62%) and 29/34 (85%) completely failed to neutralize the Zeta and Omicron variant.

For patients previously infected with the Alpha variant (n=12), geometric mean PRNT$_{90}$ titers

were 45.5 (95%CI:34.3-60) for Alpha, 27.8 (95%CI:19.8-39.0) for B.1, 7.4 (95%CI:4.0-13.5)

for Beta, 3.8 (95%CI:1.6-8.7) for Gamma, 5.9 (95%CI:2.8-12.2) for Delta, 1.6 (95%CI:0.7-

3.6) for Zeta and 0.8 (95%CI:0.4-1.7) for Omicron. Compared to the homologous Alpha variant, this results in a reduction of 1.6 (B.1), 6.2 (Beta), 12.0 (Gamma), 7.7 (Delta), 28.2 (Zeta) and 56.1 (Omicron). Complete loss of neutralization was observed for 3/12 (25%) samples for Gamma, 1/12 (8%) for Delta, 5/12 (42%) for Zeta and 10/12 (83%) for Omicron (**Fig. 1B**).

For individuals previously infected with the Beta variant (n=8), geometric mean $PRNT_{90}$ titers were 20.6 (95%CI:6.8-62.6) for Beta, 6.0 (95%CI:1.3-27.2) for B.1, 2.6 (95%CI:0.4-14.9) for Alpha, 2.6 (95%CI:0.4-15.8) for Gamma, 3.2 (95%CI:0.7-15.3) for Delta, 1.7 (95%CI:0.4-7.5) for Zeta and 0.9 (95%CI:0.4-2.3) for Omicron. Compared to the homologous virus (Beta), this results in a fold-reduction of 3.5 for B.1, 8.0 for Alpha, 7.8 for Gamma, 6.4 for Delta, 12.4 for Zeta and 23.0 for Omicron. Complete loss of neutralization was observed for 1/8 (12.5) for B.1, 4/8 (50%) for Alpha, 4/8 (50%) for Gamma, 3/8 (37.5) for Delta, 4/8 (50%) for Zeta and 6/8 (75%) for Omicron (**Fig. 1C**).

For individuals previously infected with the Gamma variant (n=10), geometric mean $PRNT_{90}$ titers were 55.6 (95%CI:24.1-128) for Gamma, 20.5 (95%CI:7.6-55.5) for B.1, 13.9 (95%CI:5.9-32.9) for Alpha, 18.3 (95%CI:8.9-37.4) for Beta, 3.2 (95%CI:1.0-10.1) for Delta, 10.2 (95%CI:5.2-20.2) for Zeta and 2.1 (95%CI:0.7-6.4) for Omicron. Compared to the homologous virus, fold reduction in neutralization was 2.7 for B.1, 4.0 for Alpha, 3.0 for Beta, 17.6 for Delta, 5.4 for Zeta and 26.9 for Omicron. Complete loss of neutralization was observed for 4/10 (40%) for Delta and 5/10 (50%) for Omicron (**Fig. 1D**). Of note, a rather strong loss of neutralization in Gamma convalescent samples was observed for Delta, while neutralization was less affected for the Zeta variant.

For individuals previously infected with Delta (n=10), geometric mean $PRNT_{90}$ titers were 72.8 (95%CI:33.9-156.2) for Delta, 25.1 (95%CI:14.0-45.1) for B.1, 18.4 (95%CI:9.5-35.4) for Alpha, 13.2 (95%CI:7.4-23.5) for Beta, 15.0 (95%CI:7.8-28.7) for Gamma, 10.4 (95%CI:4.0-26.9) for Zeta and 3.1 (95%CI:1.0-9.6) for Omicron. Fold reduction compared to homologous virus (Delta) was 2.9 for B.1, 4.0 for Alpha, 5.5 for Beta, 4.9 for Gamma, 7.0 for Zeta and 23.8 for Omicron. Complete loss of neutralization was 1/10 (10%) for Zeta and 4/10 (40%) for Omicron (**Fig. 1E**).

*Neutralizing capacity from post-vaccine and combined post-vaccine/infection-derived samples*

We investigated a total of 30 patient specimens from either double-vaccinated individuals
(n=16) or with combined vaccination-infection-derived immunity, either through prior
infection followed by vaccination, or vaccination followed by a vaccine-break through
infection with Delta or Omicron (n=14).

In contrast to all infection-derived convalescent samples, geometric mean $PRNT_{90}$ titers were
much higher for individuals double-vaccinated with either BNT162b2 or mRNA-1273 with
titers of 338.0 (95%CI:247.4-461.6) against B.1, 121.7 (95%CI:86.0-172.3) against Alpha,
49.3 (95%CI:28.1-86.8) for Beta, 62.8 (95%CI:36.0-109.5) for Gamma, 95.6 (95%CI:69.4-
131.7) for Delta, 78.5 (95%CI:50.4-122.5) for Zeta and 3.9 (95%CI:1.8-8.7) for Omicron. This
translates into a fold reduction of neutralization of 2.8 for Alpha, 6.9 for Beta, 5.4 for Gamma,
3.5 for Delta, 4.3 for Zeta and 85.7 for Omicron. No complete loss of neutralization was seen
for any VOC except Omicron in 5/16 (31%) specimens (**Fig. 2A**).

Individuals with prior SARS-CoV-2 infection before double vaccination (n=6), as determined
by presence of antibodies against the nucleocapsid, showed geometric mean $PRNT_{90}$ titers of
1190.4 (95%CI:837.8-1691) against B.1, followed by 683.2 (95%CI:516.3-904.1) for Alpha,
260.4 (95%CI:128.8-526.5) for Beta, 360.4 (95%CI:224.5-578.5) for Gamma, 494.1
(95%CI:419.4-582.1) for Delta, 351.8 (95%CI:227-545.2) for Zeta and 65.2 (95%CI:27.81-
153.0) for Omicron. Fold reduction in neutralization was 1.7 for Alpha, 4.6 for Beta, 3.3 for
Gamma, 2.4 for Delta, 3.4 for Zeta and 18.2 for Omicron. Of note, none of the specimens
showed complete loss of neutralization (**Fig. 2B**).

In addition, we have investigated vaccinated individuals with a break-through infection with
Delta (n=4) and Omicron (n=4) for neutralization against both viruses which are currently the
only VOCs co-circulating. For the first group, high geometric mean $PRNT_{90}$ titers of 1636
(95%CI: 128.2-20885) were observed for the Delta while 130.9 (95%CI:24.9-688.9) was
observed for Omicron. This results in a 12.5-fold reduction versus the homologous Delta, but
no complete loss of neutralization was observed (**Fig. 2C**). For Omicron break-through
infection following vaccination, geometric mean $PRNT_{90}$ titers were 913.5 (95%CI:341.8-
2442) was observed for Omicron, and 627.9 (95%CI:269.5-1463) was observed for Delta,
which equals a 1.5-fold loss of neutralization to heterologous Delta (**Fig. 2 D**). Highest titers
were seen against the infecting variant Omicron compared to Delta, although the prior vaccine-
derived immunity by an early pandemic spike is antigenically closer to Delta than to Omicron.

*Individual profiles of SARS-CoV-2 homologous and heterologous neutralization*

In addition to cumulated data (**Fig. 1 and 2**), neutralization profiles were also displayed on an individual basis (**Figure S1-S9**). Here, inter-individual differences both in quantity of antibody response as well as patterns of neutralization loss towards heterologous variants were observed, which does not necessarily reflect pooled results in all individuals. For example, while neutralization against Omicron was the lowest throughout convalescent samples, the differences between Alpha, Beta and Gamma were less pronounced in some individuals. Of note, in all individual comparisons, the most efficient neutralization was always observed against the homologous (infecting) strain through all convalescent sera as well as vaccine sera, when considering that the vaccine Spike most closely resembles the early pandemic variant B.1.

**Discussion**

Here we assess neutralizing capacity towards seven SARS-CoV-2 variants by convalescent specimens from individuals recovered from infection with the early-pandemic strain (pre-VOC) or the VOCs Alpha, Beta, Gamma or Delta, from double-vaccinated individuals either with or without prior infection and from double-vaccinated individuals infected with the Delta or Omicron variant.

We could show that highest SARS-CoV-2 neutralizing titers, either elicited through infection of vaccination, were always observed against the homologous strain (infecting strain or antigen used in the vaccine formulation), whereas a reduced neutralizing capacity was found for heterologous strains.

In agreement with our results, one study found lower neutralization for the Alpha and Gamma variant by pre-VOC convalescent sera and lower neutralization for pre-VOC and Alpha in Gamma infected patients, but reduced neutralization only for Gamma in vaccine sera (3.3-fold [25]. In line with these observations, Alpha-infected individuals showed reduced neutralization for the Beta variant [26]. Reduction in neutralization capacity for the Delta variant was estimated between 4- and 8-fold in vaccinated and 6-fold in convalescent sera [27]. Beyond our study, there is only a single pre-print that investigated the response to VOCs in a background

of variant-specific convalescent samples from individuals infected with pre-VOC, Alpha, Beta

or Delta samples, that showed strongest neutralization towards homologous vs heterologous

virus for Alpha, Beta and Delta convalescent-variant pairs. [28]

We observed a reduction of neutralization capacity by first-wave SARS-CoV-2 convalescent

and post-vaccine samples towards Alpha, Beta, Gamma and Delta to a comparable extent than

what was described by others [27, 29-32]. While for the Alpha variant, only slightly reduced

neutralization was described for both convalescent and vaccinee sera, a more pronounced

reduction of neutralization was observed for the Beta and Gamma variant [30, 31, 33-36]. Thus,

Beta and Gamma comprised the two VOCs with the most pronounced immune escape and at

the same time successful enough to cause larger outbreaks in defined geographic region,

without reaching global dominance in the time before the emergence of Omicron. A recent

study with pre-VOC SARS-CoV-2, Alpha and Beta in multiple animal and cell culture models

showed enhanced fitness of Alpha but not Beta which could be a reason why Alpha but not

Beta reached wide dominance in early 2021 [37].

Across our panel of convalescent and vaccine sera, the strongest decline of neutralization

capacity was observed for Zeta and Omicron. While convalescent specimens showed strong

reduction of neutralization for Zeta of up to 25.9-fold, neutralization capacity was restored in

vaccinated individuals that showed only 4.3-fold decline compared to pre-VOC SARS-CoV-

2. In contrast, for Omicron, a stark loss of neutralizing activity of up to 46-fold or 86-fold was

observed for both convalescent and vaccine sera, respectively. Thus, fold-change reduction

was even higher in vaccine sera than in convalescent sera, although titer in vaccine sera were

higher and therefore percentage of specimens with complete loss was lower (31% of specimens

vs. 83%). A similar loss of neutralization capacity against Omicron was observed in other

studies [28, 38-40], although no validation across the full range of VOC convalescent sera was

available before our data set. Interestingly, immune escape properties in terms of fold change

reduction vs. the homologous virus was overlapping between Zeta and Omicron in some

combinations, e.g. a 25.9-fold reduction of Zeta in pre-VOC convalescent samples, and a 23.0-

fold reduction of Omicron in Beta convalescent samples. Such observed differences in fold-

change reduction between Zeta and Omicron were less than 2-fold in early pandemic, Alpha

and Beta convalescent sera, showing that even before the emergence of Omicron, variants with

strong immune escaping properties almost reaching that of Omicron were already circulating

but did not become dominant. For post-Gamma and post-Delta specimens, the differences

between fold-change reduction of Zeta and Omicron were much bigger, with Omicron showing a 3-5-fold higher escape of neutralization compared to Zeta. At least for Gamma, robust neutralization for Zeta could be explained by a common origin as both are descendants from B.1.1.28 (Pango lineage) [10]. To the best of our knowledge, no data on neutralization of the Zeta variant by convalescent or vaccinee samples has been described to date, and few other data were obtained on this variant. Contrary, loss of neutralization for Delta was much more pronounced in Gamma than in any other convalescent or vaccine sera with a 17.6-fold reduction. Such strong immune escape of Delta in a variant-specific infection background has not been reported before.

Of note, we have observed large differences in the reduction of neutralization capacity across specimens with different infection background which has not been described in this detail before. While convalescent specimens of individuals infected with a pre-VOC SARS-CoV-2 and Alpha showed 45.6- and 56.1-fold reduction of neutralization capacity for Omicron, patients previously infected with the Beta, Gamma or Delta variant showed a lower reduction in neutralization capacity of 23.0, 26.9 and 23.8-fold, and a lower percentage of specimens with complete neutralization failure, respectively. These differences could indicate that regional heterogeneity in background immunity could potentially influence emergence and spread of Omicron or other future variants with immune escape properties.

A gradient of immune escape can be described from the variants investigated here, from pre-VOC to Alpha (only slight immune escape, but successfully outcompeted earlier strains), Beta and Gamma (more pronounced immune escape with regionally pronounced circulation but no global dominance) to Zeta (variant with one of the strongest escapes of immunity prior to Omicron, but limited transmission). Our data on Zeta, along with data two other VOIs Mu and Lambda, have shown the strongest escape from neutralization in pandemic period before the emergence of Omicron [41-44]. Although differences between escape from neutralization between Zeta and Omicron are only two-fold in some subgroups, neutralization for Zeta was restored in vaccinee specimens, while this was not the case for Omicron. This could hint towards different mechanisms of immune escape between SARS-CoV-2 variants.

Of note, mutation of position 484 in the receptor binding domain is found in Beta, Gamma, Zeta (E484K) and Omicron (E484A). The same mutation arose independently also in a lineage of the Alpha variant where is was also associated with escape from neutralizing antibodies[45]. It has been shown that a mutation at position 484 of the spike tends to have the strongest effect

on receptor binding and neutralization [46-49]. While the mutation can explain, at least partly,
the strong escape from neutralization in Omicron, it has no or only very low influence on
ACE2-binding and is therefore most likely not associated with higher transmissibility, although
the mechanism of transmissibility in Omicron is not well understood [50].

We have shown that Omicron exhibits a strong escape from neutralization in both convalescent
and vaccine sera, although differences in fold change reduction exist depending on prior
infection background. However, it has been shown that a third dose of a mRNA vaccine is able
to restore neutralizing capacity [51-54]. Similarly, individuals with mixed immunity, i.e.
infection prior to double vaccination, or infection after double vaccination, also leads to higher
neutralizing capacity towards Omicron [40,Rössler, 2021 #90]. With an increasing number of
vaccine break-through infections observed during the Delta wave and reports of a large number
of vaccine break-through infections with Omicron, an assessment of mixed immunity is of
huge interest, especially for protection against new variants [55]. In addition, it has been
speculated whether the immune response towards an antigenically drifted SARS-CoV-2 variant
will be influenced by pre-existing immunity [56].

Here we investigated four individuals with a Delta break-through infection after double
vaccination and have found high neutralizing titers for Delta. Neutralization capacity for
Omicron was markedly reduced, but titers were still higher than titers against other VOCs in
double-vaccinated individuals indicating that even a boost with a mismatched strain (Delta)
can lead to a considerable increase in immunity against Omicron. Similarly, vaccine break
through infections with Omicron resulted in very high neutralization titers against the Omicron
variant indicating that infection with an antigenically drifted variant led to a robust Omicron-
specific immune response despite the presence of pre-existing immunity against the original
pandemic strain. Interestingly, neutralizing titers against the Delta variant were only minimally
reduced compared to Omicron indicating that infection with antigenically different variants can
boost immunity against variants that are antigenically similar to the vaccine strain.

Population immunity and evolutionary pressure might differ on a regional scale depending on
the immunity induced by earlier circulating variants [57]. High titers of neutralizing antibodies,
such as elicited by the vaccine, were at least partially able to neutralize earlier variants before
the rise of Omicron. Form an epidemiological point of view, this highlights that vaccine-
induced immunity probably would have allowed lower virus circulation compared to immunity
induced through infections, which may have prevented the evolution of new variants that

harbor immune escape properties such as Omicron. Although the origin of Omicron is not well understood, it was speculated that a high background of Beta-variant immunity has favored the development of Omicrons immune escaping properties [58]. In contrast to earlier variants, Omicron is showing a rapid increase in cases with a short doubling time, in addition to its immune-escaping properties [59]. This, together with reduced neutralization is also suggestive of decreased vaccine effectiveness, will further complicate the management of the pandemic.

Limitations of our study are the relatively low number of specimens that were available for convalescent specimens of patients previously infected with variants. Furthermore, we cannot exclude that individuals infected with a VOC have not already been infected in 2020 with a first-wave virus and thus antibodies are derived from multiple infections with more than one variant. In addition, the Beta variant, which could not be readily isolated on VeroE6 cell lines had to be adapted to VeroE6 in order to be usable for our PRNT, thus the isolate accumulated mutations, which could affect the neutralization results. No convalescent samples were available from individuals infected with Zeta, and no convalescent samples were yet available from individuals infected with Omicron without prior vaccination. Furthermore, testing of single time points after infection/vaccination can only provide a snapshot and not inform on the duration of antibody responses over time. All our blood specimens were collected at rather early time points after infection or vaccination, thus with time, a broader neutralizing capacity towards the heterologous variant might be observed due to somatic hypermutation and affinity maturation, although in the case of Omicron most likely will not restore neutralization loss [60].

Overall, we could show that responses to variants before Omicron were associated with reduced, but not complete loss in neutralization both by infection-derived as well as vaccine derived immunity, although variants such as Zeta have already shown immune escape properties, but did not become dominant at the time of their emergence. Omicron, in contrast to earlier variants displays a strong immune escape with a surge in case numbers in many areas of the world. Furthermore, the continuous emergence of SARS-CoV-2 variants since late 2020 shows that the virus is still underlies evolutionary pressure and currently available vaccines might not be sufficient to mitigate the pandemic in the near-term future. Furthermore, whether immunity of a population was obtained by a vaccine or by previous infection with a certain SARS-CoV-2 variants could influence the type of evolutionary pressure for circulating SARS-

CoV-2 and lead to the emergence of new variants that differ for countries with major vaccine
vs. major infection-derived immunity.
