Abstract

People with knee osteoarthritis who adopt a modified foot progression angle (FPA) during gait often benefit from a reduction in the knee adduction moment and knee pain. It is unknown, however, whether changes in the FPA increase hip moments, a surrogate measure of hip loading, which may increase the risk of hip pain or osteoarthritis. This study examined how altering the FPA affects hip moments. Individuals with knee osteoarthritis walked on an instrumented treadmill with their baseline gait, 10° toe-in gait, and 10° toe-out gait. A musculoskeletal modeling package was used to compute joint moments from the experimental data. Fifty participants were selected from a larger study who reduced their peak knee adduction moment with a modified FPA. In this group, participants reduced the first peak of the knee adduction moment by 7.6% with 10° toe-in gait and reduced the second peak by 11.0% with 10° toe-out gait. Modifying the FPA reduced the early-stance hip abduction moment, at the time of peak hip contact force, by 4.3% ± 1.3% for 10° toe-in gait (p=0.005) and by 4.6% ± 1.1% for 10° toe-out gait (p<0.001) without increasing the flexion and internal rotation moments (p>0.15). In summary, when adopting a FPA modification that reduced the knee adduction moment, participants did not increase surrogate measures of hip loading.

Keywords: gait modifications, non-surgical intervention, joint loading, musculoskeletal modeling, osteoarthritis

Introduction

Of the 30 million Americans who suffer from osteoarthritis (OA) (Cisternas et al., 2016), an estimated 14 million have symptomatic knee OA (Deshpande et al., 2016). People with knee OA have a 25% lifetime risk of developing hip OA (Murphy et al., 2010) due to shared risk factors, which place multiple joints at risk for OA (Felson, 2004; Issa et al., 2012). Obesity, one of these risk factors, increases compressive loading in both the knee (Messier et al., 2014) and the hip (Lerner and Browning, 2016). These joint forces influence OA initiation and progression (Andriacchi et al., 2004; Felson, 2013). Since direct measurement of compressive joint forces in a native joint is not possible, joint moments are often used as surrogate measures of joint loading.

The knee adduction moment (KAM) is correlated with knee OA presence (Baliunas et al., 2002), knee pain (Robbins et al., 2011; Thorp et al., 2007), knee cartilage degradation (Chehab et al., 2014), and predicts knee OA progression (Miyazaki, 2002). People can change their KAM by modifying features of their gait, such as trunk sway or walking speed (Hunt et al., 2008; Mündermann et al., 2004). Gait modifications are attractive because they can potentially reduce pain without surgery or external devices. One such gait modification is changing the foot progression angle (FPA), i.e., toeing-in or toeing-out. Altering the FPA requires changes to lower-body kinematics (Shull et al., 2013) and muscle coordination (Charlton et al., 2018; Rutherford et al., 2010). Toeing-in generally reduces the first peak of the KAM (Shull et al., 2013), whereas toeing-out reduces the second peak of the KAM (Guo et al., 2007). With personalized FPA modifications, the number of individuals who can reduce their peak KAM is maximized (Uhlrich et al., 2018). Studies that evaluate the efficacy of KAM-targeted gait modifications focus primarily on the effects at the knee, although Mündermann et al. (2005) suggested the need to evaluate the effects of these modifications on other joints.

As research on FPA modifications for people with knee OA progresses towards a deployable intervention (Hunt et al., 2018; Xia et al., 2020), it is important to understand their effects more comprehensively, particularly at the hip. Increased hip moments alter the compressive loading environment in the joint (Simic et al., 2011) and are associated with hip OA symptoms (Hall et al., 2019), presence (Maly et al., 2013), severity (Diamond et al., 2018), and progression (Tateuchi et al., 2017). Some studies have examined the effect of gait modifications on hip contact forces, kinetics, and kinematics to minimize torsional loading and loosening of total hip replacements (Bowsher and Vaughan, 1995) and to reduce hip contact forces for patients with hip pathology (Wesseling et al., 2015). However, gait modifications that target knee loading have not been investigated for their effect on the hip. Therefore, an important next step is to understand how interventions that target knee loading affect hip kinetics, kinematics, and spatiotemporal parameters of gait.

This study analyzes the biomechanical effects of a FPA modification on the hip in individuals with medial compartment knee OA. The purpose of this research is twofold: (1) determine if FPA modifications increase peak hip moments and (2) understand the lower-extremity kinetic, kinematic, and spatiotemporal parameter changes that occur when modifying the FPA. Our results provide insight into whether gait modifications for knee osteoarthritis could have unintended deleterious effects at the hip.

Methods

Data Collection

Participant data were analyzed from a clinical study (clinicaltrials.gov NCT02767570) that trained people with medial compartment knee OA to walk with a modified FPA to reduce

their peak KAM. One hundred seven people provided informed consent in agreement with a Stanford University Institutional Review Board approved protocol. Inclusion criteria included medial compartment knee OA grade between one and three on the Kellgren-Lawrence scale from anterior-posterior weightbearing radiographs; medial knee pain of three or greater on an 11-point numeric rating scale; the ability to walk safely on a treadmill without assistance for 25 minutes; and BMI less than 35. The limb examined for each participant was chosen based on the presence of radiographic and symptomatic medial knee OA. If medial knee OA was present in both knees, the more symptomatic side was analyzed.

The data collection methods have been detailed previously (Uhlrich et al., 2020) and are outlined here. Experimental gait data were collected during a visit where different FPA modifications were evaluated for their effect on KAM peaks (Uhlrich et al., 2020). First, a standing calibration trial was performed, followed by a functional hip joint center calibration trial during which participants were asked to circumduct their hips (Piazza et al., 2004). Participants then walked naturally at a self-selected speed on an instrumented split belt treadmill (Bertec Corporation, Columbus, OH, USA) while ground reaction force data and optical marker positions were recorded (Motion Analysis Corporation, Santa Rosa, CA, USA). Vibrotactile biofeedback (Engineering Acoustics, Casselberry, FL, USA) was given to teach participants to toe-in and toe-out by 10° relative to their natural FPA. The absolute FPA was calculated as the angle between the line connecting the calcaneus and second metatarsal head marker positions and the forward direction of the treadmill during 15-40% of stance (Rutherford et al., 2008).

Of the one hundred seven participants who completed this task in the clinical study, fifty were included in this analysis (Table 1). Selection for this analysis required participants to reduce the first or second peak KAM by at least 5% with either a 10° toe-in or a 10° toe-out gait

modification as compared to baseline. The first and second peak of the KAM were defined as the maximum values during 0-50% and 51-100% of the stance phase, respectively. Participants were excluded from this analysis if they used the treadmill handrails during walking trials or had greater than an estimated 1 cm of soft tissue between the anterior superior iliac spine marker and the anatomical bony landmark.

Musculoskeletal Modeling

A multicompartment knee model (Lerner et al., 2015) with adduction and flexion degrees of freedom was incorporated into a full-body musculoskeletal model with 25 degrees of freedom and 80 muscle-tendon units (Rajagopal et al., 2016). The arms were removed from the model and the metatarsophalangeal joints were locked.

Scaling the generic musculoskeletal model to match the dimensions of each subject was a two-step process. First, long-leg radiograph measurements were used to adjust frontal plane tibiofemoral alignment and pelvic width. The frontal plane leg alignment was found by measuring the angle (ImageJ, National Institute of Mental Health, Bethesda, Maryland, USA) between a line connecting the hip and knee joint centers and a line connecting the knee and ankle joint centers (Lerner et al., 2015). The pelvic width was defined as the distance between the hip joint centers identified on radiograph. Second, the remainder of the model bodies were scaled using locations of joint centers and anatomical markers in OpenSim 4.0 (Seth et al., 2019).

Inverse kinematics was performed to compute hip adduction, flexion, and internal rotation angles. Results were filtered with a 4th order Butterworth filter and cutoff frequency of 15Hz. These kinematics and ground reaction forces, also filtered at 15 Hz, were used in inverse dynamics to calculate external hip abduction, extension, and internal rotation moments.

Data and Statistical Analysis

For each gait trial (baseline, 10° toe-in, and 10° toe-out), the last 20 steps that achieved the target FPA, within 2.5°, were analyzed. Each biomechanical metric of interest was calculated for every step and averaged over each walking condition.

Hip moments were normalized by participant mass and compared between walking conditions for two primary kinetic metrics: the early-stance hip moment and angular impulse. To estimate the hip moment at the time of greatest hip loading, the early-stance hip moment was computed as the average moment during 15-20% of stance phase, the time of first peak hip contact force (Bergmann et al., 2001; Wesseling et al., 2015). For analysis during the entire stance phase, the angular impulse was computed as the area under the moment absolute value curve during stance phase. The sum of the angular impulse in the frontal, sagittal, and transverse planes defined the cumulative angular impulse. For kinematic analysis, joint angles were averaged during stance and compared between walking conditions to capture global changes. Peak angles were also compared between conditions. Spatiotemporal parameters were also determined for comparison, including FPA, stride length, and step width. Stride length was defined as the difference in right and left foot calcaneus marker positions at time of heel strike. Step width was defined as the distance between the right and left foot center of pressure at 50% of stance (Donelan et al., 2001).

Statistical comparisons of 10° toe-in and 10° toe-out gait metrics compared to baseline were performed in MATLAB R2020a (MathWorks Corporation, Natick, MA USA) using a Wilcoxon signed-rank test ($\alpha = 0.05$). Bonferroni corrected p-values for multiple comparisons across FPA conditions were reported to mitigate type I error.

Results

Participants adopted an FPA modification that reduced the peak knee adduction moment and did not increase surrogate measures of hip loading. On average, 10° toe-in modifications reduced the first peak of the KAM by 7.6% compared to baseline, and 10° toe-out reduced the second peak by 11.0%. The early-stance hip abduction moment was significantly lower during 10° toe-in gait (-4.3% ± 1.3%; p=0.005) and during 10° toe-out gait (-4.6% ± 1.1%; p<0.001) compared to baseline. There were no significant differences (p>0.05) in the early-stance hip extension moment or early-stance internal rotation moment for 10° toe-in or toe-out conditions compared to baseline (Figure 1, Figure 2).

The frontal plane angular impulse was significantly reduced compared to baseline for 10° toe-in gait (-2.3% ± 0.7%, p<0.01) and for 10° toe-out gait (-6.9% ± 0.8%, p<0.001), but no significant differences (p>0.05) were observed in the sagittal or transverse plane (Figure 2). There was no difference in the cumulative angular impulse for 10° toe-in gait compared to baseline; however, the 10° toe-out cumulative angular impulse was significantly lower (-3.6% ± 0.7%, p<0.001). While on average there were no increases in the cumulative angular impulse, some individuals experienced increases. The largest observed cumulative angular impulse increase from baseline was 7.7% and 9.2% for 10° toe-in and 10° toe-out gait, respectively.

Changes in hip kinematics were minimal. Participants walked with a decreased *average* hip adduction angle for 10° toe-in gait (-0.4° ± 1.1°, p=0.045) and 10° toe-out gait (-1.6° ± 1.2°, p<0.001) compared to baseline (Figure 4). *Peak* hip adduction angles also decreased for both toe-in (-0.7° ± 1.5°, p=0.009) and toe-out (-1.8° ± 1.5°, p=0.005) gait compared to baseline. Participants walked with increased *average* hip flexion when toeing-in (2.7° ± 2.2°, p<0.001) and toeing-out (1.7° ± 2.1°, p<0.001). Both modifications had a lower *peak* extension angle compared to baseline (toe-in: -3.2° ± 2.7°, p<0.001; toe-out: -2.5° ± 2.7°, p<0.001). The *average*

hip internal rotation angle increased by an average of 4.4° ± 2.6° (p<0.001) when walking with a

10° toe-in gait and decreased by 5.7° ± 1.3° (p<0.001) with a 10° toe-out gait. Similar directional

changes were seen in the *peak* hip internal rotation angle compared to baseline (toe-in: 4.6° ±

2.7°, p<0.001; toe-out: -5.8° ± 1.6°, p<0.001). Changes in spatiotemporal parameters were also

observed. Stride length decreased with both FPA modifications (p<0.001), while step width

increased only for 10° toe-out gait (p<0.001) (Table 2).

Discussion

We analyzed how changing the FPA during walking affects hip moments in fifty

individuals with medial knee OA. Both 10° toe-in and 10° toe-out modifications decreased the

early-stance hip abduction moment and the frontal plane angular impulse. On average, adopting

an FPA modification, that reduced the KAM, did not significantly increase the hip moments at

time of peak hip contact force, the angular impulse, or the cumulative angular impulse. This

suggests that this intervention may not increase hip loading and place the hip joint at increased

risk of OA in most participants. However, some participants did increase their cumulative

angular impulse moment with the FPA modification, which could be detrimental to hip joint

health. For people with hip joint pathology, or who are at high risk of developing hip OA, the

effect of a FPA gait modification at the hip should be evaluated individually.

Our observed decrease in the hip abduction moment is consistent with other studies. The

4% decrease in the early-stance hip abduction moment when toeing-in and toeing-out was

smaller than the 16% decrease observed at the time of peak KAM in a healthy population

(Kettlety et al., 2018), which could be due to the varying participant population and period of the

gait cycle when the moments were analyzed. Similarly, the reductions in early-stance hip

abduction moment (10° toe-in: 0.03 Nm/kg; 10° toe-out: 0.04 Nm/kg) agreed directionally with the 0.1 Nm/kg decrease Wesseling et al., (2015) reported from simulated perturbations of frontal plane hip kinematics. The magnitude differences are unsurprising when comparing simulation predictions to experimental results.

Kinematic and spatiotemporal changes were also observed when participants modified their FPA. Changes in the hip rotation angle were less than the change in FPA, which aligns with results from Cibulka et al., (2016), who found that FPA modifications elicit changes at multiple lower-extremity joints. In addition to the rotational kinematics changes, the average hip adduction angle decrease relates to the increase in step width for toe-out gait. Other studies (Kettlety et al., 2020; Uhlrich et al., 2018) have also observed that step width increases with a modified FPA resulting from less hip adduction. While the decrease in hip adduction angle and increase in step width are small, these changes increase medio-lateral stability (Meyer et al., 2018). Additionally, participants decreased stride length, which can increase double-limb support time, resulting in a more stable gait (Shkuratova et al., 2004). The changes to kinematics and spatiotemporal parameters may attenuate over time as an individual becomes more comfortable with the gait modification.

It is important to identify the limitations of our study. First, we estimated the effect of FPA modifications on surrogate measures of hip loading. Electromyography was not used in this study, but, in the future, validated electromyography-informed simulations could estimate changes in muscle and hip contact forces. The surrogate measure of hip loading that we used, joint moments, is related to muscle and joint contact forces, which provides an estimate of the directional change in hip contact force. Meyer et al. (2018) reported that a decrease in the hip abduction moment and hip adduction angle reduced the work generated by the hip abductor

muscles and decreased hip loading in people with hip OA. Second, it is challenging to accurately measure axial rotations at lower-extremity joints with optical motion capture (Gorton et al., 2009). Fluoroscopy could be used in future studies to assess the distribution of axial rotations more accurately across lower-extremity joints.

Several studies have shown that foot progression angle modifications can provide meaningful reductions in the knee adduction moment. Our results add to this growing body of evidence and show that foot progression angle modifications reduced frontal plane hip moments without increasing the moments in other planes. This suggests that changes in foot progression angle that aim to reduce knee loading, on average, do not increase surrogate measures of hip loading. Results from this study, and our previous study (Uhlrich et al., 2020), suggest that changes in foot progression angle during gait should be personalized to determine the best intervention for each individual.

Age (yr)	61.34 (7.81)
Height (m)	1.72 (0.11)
Mass (kg)	76.24 (15.43)
BMI (kg/m^2)	25.77 (3.83)
Gender	M: 31 F: 19
Static Knee Angle (°): Varus (-) Valgus (+)	Ipsilateral: -2.38 (3.56) Contralateral: -1.02 (3.58)
Participants who reduced peak KAM with a modified FPA	Peak 1 only: n =11 Peak 2 only: n =14 Peak 1 & Peak 2: n =25
Gait Speed (m/s)	1.24 (0.12)
Kellgren and Lawrence Grade	□: 12, □: 27, □: 11
Medial Knee Pain: 0 (no pain) - 10 (worst pain)	4.39 (1.64)

Table 1: Demographics of the fifty participants with symptomatic medial knee osteoarthritis included in the analysis. Standard deviation (SD) is reported in parentheses.

Parameter	Baseline		10° Toe-in			10° Toe-out		
	mean	SD	mean	SD	p-value	mean	SD	p-value
FPA (°)	6.88	3.46	- 2.79	3.49	**< 0.001**	16.53	3.41	**< 0.001**
Stride Length (m)	1.33	0.14	1.29	0.13	**< 0.001**	1.29	0.13	**< 0.001**
Step Width (m)	0.18	0.04	0.19	0.04	0.8629	0.22	0.05	**< 0.001**
1st Peak KAM (%BW/H)	3.69	1.17	3.41	1.11		3.80	1.23	
2nd Peak KAM (%BW/H)	2.72	0.98	2.72	1.01		2.42	1.06	

Table 2: Spatiotemporal parameters and KAM outcome measures for participants during baseline gait, 10° toe-in and 10° toe-out. Note, p-values are not reported for the peak KAM values since participants were selected based on their ability to reduce their peak KAM.

Figure 1: Participants reduced their early-stance hip abduction moment for 10° toe-in (blue) and 10° toe-out (red) gait as compared to baseline. No significant differences were observed between baseline gait and toe-in or toe-out gait for the early-stance hip extension and internal rotation moment. (*$p<0.005$)

Figure 2: Ensemble-averaged hip moment curves, normalized by bodyweight, for all participants (n = 50) during stance phase. Baseline gait (black, dashed) hip moments are compared to 10° toe-in gait (blue, solid) in the first row and 10° toe-out gait (red, solid) in the second row. The shaded region indicates one standard deviation from the average moment.

Figure 3: Participants reduced their frontal plane angular impulse during 10° toe-in (blue) and 10° toe-out (red) gait compared to baseline. No significant differences were observed between baseline and toe-in or toe-out gait for the angular impulse in the sagittal and transverse plane. (*p<0.01)

Figure 4: Ensemble-averaged hip kinematics for all participants (n = 50) during stance phase. Baseline gait (black, dashed) hip angles are compared to 10° toe-in gait (blue, solid) in the first row and 10° toe-out gait (red, solid) in the second row. The shaded region indicates one standard deviation from the average hip angle. The peak hip adduction angle and the peak hip extension angle are significantly reduced with 10° toe-in gait and 10° toe-out gait compared to baseline (p<0.01). The peak hip internal rotation angle is significantly increased for 10° toe-in gait and reduced for 10° toe-out gait compared to baseline (p<0.001).
