Running title: Vaginal metagenomics and endometrial cancer

Conflicts of Interest: The authors declare no potential conflicts of interest.

Key Words  
Endometrial cancer, low-grade, high-grade, microbiome, metagenomics
Abstract

Background: The vaginal microbiome is an underexplored environment which may yield insights about endometrial cancer (EC) pathophysiology and serve as an early marker of disease. Our objective was to evaluate the preoperative vaginal microbiome in women undergoing hysterectomy for benign conditions and EC to identify patterns which could segregate benign disease from EC, and to assess if the microbiome distinguishes low-grade (LG) from high-grade (HG) histologies.

Methods: Vaginal microbiome samples were prospectively collected at the time of hysterectomy, and clinicopathologic data collected. Extracted DNA underwent shotgun metagenomics sequencing. Microbial diversity was calculated using the Shannon Index (α-diversity) and PERMANOVA (β-diversity). Hierarchical clustering was used to describe community state types (CST), which were then compared by microbial diversity and grade. Machine learning was utilized to assess the predictive value of grade and histology based on relative bacterial abundance.

Results: 61 patients participated: 1) benign gynecologic disease (n=11), 2) LG EC (n=30), and 3) HG EC (n=20). 40 (62.5%) were White, 22 (34.3%) were Black, and 37 (57.8%) were Hispanic. Both α- and β-diversity were associated with tumor grade (p=0.026 and p=0.035, respectively). Four CST were identified that associated with grade of disease (p=0.036). Different histologies demonstrated variation in CST even within tumor grades (p=0.017). Markers at the species level informed models that predicted benign vs cancer (AUC 0.878), HG versus benign (AUC=0.803), and HG versus LG (AUC=0.771) with high accuracy.

Conclusions: The vaginal microbiome segregates benign disease from EC, and is predictive of histology and grade, suggesting it may be an effective tool for screening.
Introduction

Endometrial cancer is the most common gynecologic malignancy in the United States (1). The incidence of this disease has been increasing, and it is now listed as one of the leading causes of cancer death in women (1, 2). Aside from stratification by epidemiologic risk factors and genetic predisposition (3), there are no routine screening practices for endometrial cancer and women usually present when they develop symptoms. Unfortunately, knowledge of these symptoms is generally poor (4), potentially putting patients at risk for prolonged periods before oncologic evaluation.

While genomic classifications have been suggested to better distinguish between subtypes of endometrial malignancies (5), due to restrictions in cost and expediency required for treatment initiation, the histologic characterization of disease finds more clinical relevance in practice. Type I, or low-grade tumors, are driven by an overabundance of estrogen. These primarily glandular tumors with endometrioid histologies are commonly symptomatic early, diagnosed at earlier stages, and can in many cases be successfully treated with surgery alone. In contrast, type II, or high-grade tumors are characterized by aggressive presentations, often with metastatic disease at diagnosis as they may not be symptomatic in early stages (6). Comprised predominantly of serous, clear cell, carcinosarcoma, high-grade endometrioid, and undifferentiated histologies, type II malignancies have worse survival.

The human microbiome has been shown to influence cancer risk and outcomes by a number of mechanisms, including influencing inflammation, altering the genomic stability in host cells, and producing oncometabolites (7). Defining the microbiome by community state types (CST), which are groups of microbes of similar phyla and abundance, has been useful to describe differences across groups of women, but utilization of CSTs to assess clinical endpoints in endometrial cancer has not previously been described. Because endometrial cancer is a heterogeneous disease comprised of differing histologies and biologic drivers of malignant transformation, comparisons of microbial communities relative to specific histologies and grades may vary and suggest additional unexplored pathways for disease pathogenesis and propagation.

Our primary objective was to conduct an exploratory analysis to characterize the preoperative vaginal microbiome in women undergoing surgery for endometrial cancer using metagenomic analyses. The
secondary objective was to identify patterns which would reliably segregate not just benign from malignant disease, but also distinguish low-grade from high-grade tumors, as guided by CSTs. Such data may identify opportunities for utilization of the vaginal microbiome in the screening of endometrial cancer, and suggest alternative, unexplored mechanisms of disease pathogenesis.

**Materials and Methods**

**Ethical Approval and Consent**

Approval for this study was provided by the Institutional Review Board at the University of Miami (protocol #20170660). Informed consent was obtained from all participating patients, with forms provided in English, Spanish, and Haitian Creole. This cross-sectional study is reported in accordance with the Strengthening the Reporting of Genetic Association Studies (STREGA) reporting guideline (8). Patients were consented between February 2018 and October 2018 in a sequential manner without any preplanned stratification. The initial protocol called for an over-sampling of uterine serous carcinoma (planned accrual n=10).

**Population for Study and Patient-related information**

Three groups of patients were recruited for the study: 1) Women with benign gynecologic disease undergoing elective surgery for non-malignant conditions, such as fibroids or endometriosis; 2) Women with low-grade (LG) endometrial carcinoma (EC), defined as endometrial intraepithelial neoplasia (EIN), grade 1 or grade 2 endometrioid adenocarcinoma on preoperative endometrial biopsy or uterine curettage; 3) Women with high-grade (HG) endometrial carcinoma, defined as grade 3 endometrioid, serous, small cell, clear cell, undifferentiated, or dedifferentiated carcinoma, or uterine carcinosarcoma, on preoperative endometrial biopsy or uterine curettage. Patients were enrolled sequentially with no planned matching.

Women were required to be ≥18 years of age, able to provide written consent, and able to read and understand English, Spanish, or Haitian Creole. All patients underwent surgery at one of the hospitals affiliated with the physician practice: University of Miami Hospital (UMH), Sylvester Comprehensive Cancer Center (SCCC), or Jackson Memorial Hospital (JMH). Patients were excluded if they had an active
gynecologic infection on physician assessment, had any contraindication to the introduction of a swab into
the vagina (e.g. severe vaginal stenosis), administration of neoadjuvant chemotherapy, douching within 14
days of surgery, use of vaginal cream or lubricant within 14 days of surgery, or sexual intercourse within
five days of surgery.

Patient-specific information was collected from the electronic medical record, including: age at
diagnosis, race, ethnicity, final histologic diagnosis, tobacco use, body mass index (BMI), presence of
lymphovascular space invasion (LVSI), and results of high-risk HPV DNA testing from most recent Pap
smear.

Specimen collection and processing

On the day of surgery, following induction of anesthesia, and prior to both vaginal preparation with
betadine/chlorhexidine and administration of prophylactic antibiotics, the vaginal swab (4N6FLOQSswab,
ThermoFisher, #4473979) was placed into the vagina by the attending physician, with care to ensure contact
of the swab with the cervix, posterior fornix of the vagina, and vaginal sidewalls. The swab was
immediately transferred to the bead tubes which were then snap frozen and kept at –80°C. Microbial DNA
was extracted with the PureLink microbiome DNA purification kit (ThermoFisher, Invitrogen, #A29790)
following manufacturer’s protocol. DNA was eluted in 50ul of AE buffer and quantified using a NanoDrop
2000c Spectrophotometer (Thermo Fisher). Additional details regarding DNA library construction and
sequencing can be found in S1.

Statistical analyses

Statistical analyses were performed using custom scripts written in the statistical language R for
Statistical Computing. To avoid bias, all patients were included in the analyses, even when missing specific
data points, and all available data were included. Summary statistics were used to describe the entire cohort.
Significant differences among patient clinical characteristics were determined using Kruskal-Wallis and
Wilcoxon signed rank test. The false discovery rates (FDR) were controlled by applying the Benjamini-
Hochberg procedure. All tests were two-sided, with significance set at \( p<0.05 \). Explanation of the power calculation can be found in S1.

**Alpha and beta microbial diversity**

Alpha (\( \alpha \)) and Beta (\( \beta \)) diversity are standard ecological measures of microbial diversity representing, respectively, the number of unique taxa per sample and similarity in composition between samples. We calculated the observed number of operational taxonomic units (OTUs) as the \( \alpha \) diversity measure for each sample within the tumor type groups after rarefaction. We also calculated the Shannon index as our main \( \alpha \)-diversity metric, which was generally concordant with observed number of species. We then fitted a linear model for independent samples. The t-type was used to determine statistical significance. For \( \beta \) diversity, we rarefied the data prior to calculating the various distance measures. To test the association between the covariates and \( \beta \)-diversity measures, we used PERMANOVA, a distance-based analysis of variance method based on permutation. An omnibus test, which is a permutation test taking the minimum of the P-values of individual \( \beta \)-diversity measures as the test statistic, was used to combine multiple sources of association evidence provided by different \( \beta \)-diversity measures and an overall association P-value was reported. Ordination plots were generated using classic multi-dimensional scaling (MDS). Analyses of the effects of covariates is provided in S2.

**Vaginal community state typing**

Briefly, a matrix of sample dissimilarity was created based on the relative abundance of microbial species in each sample using Bray-Curtis distance method. Community State Types (CST) were generated to classify the vaginal microbial communities, to explore community structure, and to reduce dimensionality based on previous reports (9, 10). Samples were clustered into four CSTs using the dissimilarity matrix as the input and Ward’s hierarchical clustering as the method, which minimized the total within-cluster variance. We used gap statistics to determine the optimum number of clusters in the dataset. Considering the sample size, we used \( k=4 \) as the optimum number of clusters.
Differential abundance analysis

We performed microbiome-wide analysis to identify phylum, family, genus, and species that were differentially abundant between samples with different tumor grades and histology. Using phyloseq_to_deseq2 from phyloseq package (11) we transformed microbial relative abundance data into a DESeq dataset with dispersions estimated. We then identified differentially abundant taxa species using the Wald tests from R package DESeq2. We used samples’ species abundance without rarefying to account for variability in read depth between samples. Reported $p$-values were adjusted by the false discovery rate ($p$-adj $< 0.05$)

Gene Expression and Pathway Analysis

We used VIRGO (9) to identify and quantify community gene content, or gene richness, defined as the abundance of non-redundant genes. Non-redundant genes were also annotated with a rich set of functional descriptions. For gene set enrichment analysis (GSEA) (12) we conducted enrichment analysis after constructing gene sets: over-representation and under-representation analyses across pathologies: benign, low-grade EC, high-grade EC and tumor vs benign. We ranked genes based on their fold change between two sample groups using DEseq2 (13). Then using the fgsea R package, we performed GSEA with three gene sets including KEGG (14), Gene Ontology (GO) (15), and EggNOG, (v.5) (16). Significantly enriched gene sets were filtered based on a cutoff of $q < 0.01$.

Machine Learning for Biomarker Discovery

Construction and evaluation of machine learning models on the basis of microbial species was performed using SIAMCAT (17). Read counts at the species level were converted to relative abundances. Species with an overall abundance lower than 0.01 were removed. The statistical association between species and tumor types (or historical types) was measured using Wilcoxon test. FDR was used to correct for multiple testing. Generalized fold change and the prevalence shift between samples with different tumor (or histological) types were calculated for each species.
Results

Demographics

The clinical and demographic characteristics of the studied cohort are displayed in Table 1. Patients with HG-EC were older than LG-EC and benign patients (q=0.024). There was a significant difference in BMI between benign, HG-EC, and LG-EC patients (q=0.041). More non-Hispanic patients were in the HG-EC cohort versus the LG-EC, in which there were more women of Hispanic ethnicity (q=0.036). There were no differences in tobacco use, human papillomavirus (HPV) status, or race across the three groups (all p>0.05).

Composition of the vaginal microbiome

The metagenomics data resulted in 4.8% of sequence reads as non-human, of which 64% were taxonomically assigned to 4 major groups: bacteria, archaea, fungi, and viruses. The samples contained 237 bacterial species, representing a majority of previously described vaginal species(18). The most abundant phyla in all samples were *Firmicutes, Actinobacteria*, and *Bacteroidetes* (Fig 1). The most abundant species (based on total abundance over all samples) were *Gardnerella vaginalis, Lactobacillus iners, Streptococcus agalactiae*, and *Lactobacillus gasseri*. The most prevalent (proportion) species (present in all samples) were *Candidatus pelagibacter, Fusobacterium ulcerans, Gardnerella vaginalis*, and *Lactobacillus gasseri*. There was a significantly greater abundance of *Fusobacterium nucleatum* in HG relative to benign samples (log fold-change (FC) 4.3, p=0.02); an increase in the abundance of *Fusobacterium nucleatum* was also seen in LG samples relative to benign, but was not significant (log FC 2.4, p=0.066, S3).

Vaginal microbiota diversity

The vaginal microbiome was significantly different across α- (within samples) and β- (between samples) diversity in patients with the three disease conditions under investigation. Microbial diversity was measured using the Shannon index which accounts for both richness and evenness. Both α- and β-diversity were associated with patient tumor grade (pα = 0.026 and pβ = 0.035, respectively).
The α-diversity of LG-EC patients was not significantly different from benign or HG patient samples, however there was a significant increase in diversity from benign to HG disease (q=0.016). This trend suggests that HG disease coincides with a more diverse community of patient’s vaginal microbiome.

The PERMANOVA test was used to quantify beta-diversities based on various clinical variables. Specifically, we evaluated whether tumor types and clinical factors - histology, race, ethnicity, age, BMI and presence of lymphatic vascular invasion (LVSI) - were a significant source of β-diversity, which quantifies dissimilarities of microbial communities based on their composition. Samples grouped by clinical/demographic variables resulted in only one significant difference in microbial diversity (age p=0.049). Meanwhile, both tumor related variables (grade, histology) resulted in significant p-values (grade: p=0.022, histology: p=0.023). This suggests that sample groups are more distinct in their microbial communities based on tumor-related factors than clinical/demographic factors (S4).

Community State Type Composition and Structure

Four major community state types (CSTs) were identified with significant differences in microbiome composition, diversity, and structure. Each of the four identified CSTs was comprised of communities disproportionately composed by different phyla (Fig 2A). Bacteroidetes was absent in CST2, and Fusobacteria absent in CST1. Acinetobacteria and Firmicules were variably present across all four CSTs. The most diverse and taxonomically rich cluster was CST4; the least was CST2.

There was statistically significant clustering into CSTs by both grade and histology (Fig 2B-2C). Benign disease predominantly clustered in CST1, while LG clustered in CST2, and HG into both CST3 and CST4 (p=0.036). There was also variation in CST clustering by histology (p=0.017). Clinical characteristics and CSTs were evaluated against microbial diversity; only grade and histology had significant associations (Table 2).

Differential abundance analysis
Differential abundance (DA) analyses were conducted to determine the vaginal microbial species enriched or depleted consistently in EC communities. The comparison of average relative abundance between benign versus tumor (LG + HG) revealed that profiles obtained from tumor have only five species with statistically significant DA relative to benign samples (Fig 3, S5). Dividing tumor samples into LG and HG profiles identified 30 DA species between HG and LG as well as 17 DA species between HG and benign samples. Noticeably the abundance of 46 species is significantly lower in the HG sample compared to other sample groups. However, two species (*Fusobacterium ulcerans* and *Prevotella bivia*) were found with higher abundance in HG samples. Between LG and benign groups, there were 5 species with significantly greater abundance in the tumors; only *Staphylococcus epidermidis* demonstrated lower abundance.

**Gene expression and pathway analyses**

The metagenomic approach used allows us to investigate gene abundance and thus pathway analyses of the microbiota observed across endometrial pathologies and endometrial cancer histotypes. The HG communities were typically categorized as low gene count as 73.8% of them had less than 1000 genes. Benign communities commonly displayed high gene count as 65% of them had more than 1000 genes. Hierarchical clustering of the profiles was performed using ward linkage based on their Euclidean distance, the result of correspondence analysis conducted for gene richness and diagnosis. We found a strong dependence between the three gene-based clusters and the three tumor grades (p.value =0.025, Chi-square test). The gene-based clusters, however, were independent of other clinical variables including race, ethnicity, BMI groups, age, and disease stage (p.values: 0.64, 0.37, 0.37, 0.08, and 0.22 respectively)(S6, S7).

Using VIRGO, each non-redundant gene was taxonomically and functionally annotated. We next identified significant associations (FDR p < 0.05) between microbial abundance, gene family, and pathway abundance first across tumor and benign, and then more specifically across benign, LG-EC and HG-EC. Kegg pathway analysis of tumor versus benign had the highest number of p<0.05 statically significant associations. Purine metabolism and ABC transporter pathways were up-regulated in tumors whereas genes
associated with viral myocarditis, aminoacyl-tRNA biosynthesis and glutathione metabolism were downregulated in the endometrial tumor microbiota (S8A). Additional analyses of the metagenome of HG endometrial cancers alone compared to benign revealed the only pathway significantly upregulated is biosynthesis of siderophore group non-ribosomal peptides. Conversely, pathways downregulated included the pyrimidine metabolism, purine metabolism, homologous recombination, and ABC transporters (S8B). The downregulation of gene sets in homologous recombination, mismatch repair and ABC transporters was unique to HG-EC microbiota while ABC transporter pathway was up in the combination tumors.

**Biomarker Discovery**

To examine the diagnostic value of the vaginal microbiome, we constructed random forest (RF) models that could specifically classify samples according to patients’ tumor types including a) benign vs. tumor samples b) HG tumors vs. benign, and c) HG tumors vs LG tumors. To detect useful species markers of tumor, we conducted a fivefold cross-validation on a random forest model between case and control samples in the discovery phase. For each model a different set of species was identified as an optimum microbiome signature, consisting of a various number of features and performance of the constructed models based on the area under the receiver operating characteristic (ROC) curve (Fig 4A,4C,4E). The tumor vs benign model selected 3 important species. The discriminant model based on the abundance of these species effectively distinguishes tumor from benign disease (mean prediction AUC = 0.878, Fig 4B). Two other RF models generated from additional species abundance distinguished HG from benign, and LG from HG with AUC of 0.80 and 0.77 respectively (Fig 4D-F).

We examined the performance of models trained by samples labeled according to histologic subtype (e.g. serous, endometrioid) (S9). The highest prediction performance obtained from the model that trained to distinguish benign samples from samples labeled as serous EC (mean AUC=0.826) followed by two models that distinguish benign from endometrioid samples (mean AUC=0.795) and serous from endometrioid (mean AUC=0.776). Each of these three histologic classifier models are based 50, 60, and 65 biomarker species, respectively.
Discussion

Among patients with EC, the vaginal microbiome demonstrates significant variation by tumor pathologic characteristics. This investigation establishes that not only do prominent species vary by grade, but so too do microbial abundance and CST. These findings represent a novel perspective on the microbial content of the vagina and how the confluence with the uterus may provide opportunities for EC screening and further exploration of the role of the microbiome in disease development.

There have been few studies about the vaginal microbiome in patients with EC. In 2016, Walther-Antonio et al assessed the microbiome (16S) of the entire gynecologic tract of 17 patients with EC and 10 with benign uterine conditions. The authors reported that the microbiome across different gynecologic sites was significantly correlated, suggesting that vaginal sampling is an accurate surrogate of the microbiome within the uterus. Subsequent investigations have also confirmed that the vaginal microbiome mirrors that of the upper genital tract among women with cancer (19). Additionally, it was reported that the pattern of presence/absence of *Porphyromonas* and *Atopobium* species was predictive of EC (AUC 0.90)(20). Within our cohort, neither of these phyla demonstrated significant abundance. In contrast to the Walther-Antonio study, however, we assessed specific tumor grade relative to benign conditions. Additionally in their study all EC patients were White; 37% of our population was Black. Microbial diversity has been shown to be greater in Black versus White women (21), and CST in premenopausal women defined by Lactobacillus varies across all races (Black versus White versus Asian)(22), so the differences in the populations between our two studies may account for the discrepancy.

A follow-up study by Walsh et al. which included 56 patients with endometrioid histology and 10 with non-endometrioid, high-grade, histology, also reported that *Porphyromonas somerae* was a predictive biomarker in EC, and that additional sensitivity to disease detection was added by including patient-specific factors such as BMI, vaginal pH, and menopausal status (19). While we did not assess vaginal pH in the current study, we found no association between age or BMI and microbial diversity (Table 2). Our methodology, however, differed in that our data were segregated categorically to represent clinically meaningful groups (i.e. BMI following WHO categorization; age of 50 serving as a surrogate for
menopause). This variation in analysis may account for our findings, but may again be reflective of differences in the population of study relative to our own, as 97% of the Walsh cohort was White and only 10 patients had HG cancers. As microbial diversity in the current study was associated with tumor factors only (grade and histology) and not with categorical clinical factors, it suggests that patient-specific factors may not necessarily need to be included in a predictive model for screening.

While the differential phyla abundance between benign and tumor provides some insight into the local vaginal environment, differences in species abundance may also be meaningful in terms of tumor pathogenesis. *Prevotella bivia*, with greater than a 6-fold abundance in HG vs LG, is associated with pelvic inflammatory disease and bacterial vaginosis. *P. bivia* has been shown to upregulate proinflammatory (LAMP3, STAT1 and TAP1) genes in cervical cancer (23). Furthermore, Lactobacillus spp, which are underrepresented in HG vs benign and HG vs LG, are known to inhibit *P. bivia* (24). *Bifidobacterium longum* was the most greatly suppressed species in terms of abundance in HG vs LG disease. *B. longum* has been shown to have low relative abundance in patients with the most aggressive forms of gastric cancer, suggesting it may be protective (25). It has also been shown to improve immune-mediated tumor control (26). *Fusobacterium ulcerans* also demonstrated higher abundance in HG. This species has an association with cellular ulceration by secretion of high levels of butyrate (27); very little data exist about its role in cancer pathogenesis. *Fusobacterium nucleatum*, though not one of the most abundant species contributing to the predictive models, but with a greater than 4-fold presence in HG vs benign, has been found to promote tumor growth (28), associate with high microsatellite instability (29), and induce chemotherapy resistance (30). Patients with cervical cancer who have high levels of intratumoral *F. nucleatum* have worse progression free and overall survival (31). In colorectal cancer (CRC), the bacterium secretes the adhesin Fap2, which binds to galactose N-acetyl-D-galactosamine (Gal-GalNAc), facilitating the enrichment of tumor cells (30). Gal-GalNAc levels have been shown to be higher in uterine adenocarcinomas relative to benign endometrium (32), and over-expression of the transferases that facilitate Gal-GalNAc glycosylation are strongly associated with histologic grade of tumor and myometrial invasion (33). In CRC cells in vitro, a high abundance of intratumoral *F. nucleatum* also activates autophagy, thus inducing resistance to platinum-
based chemotherapy (30). The role of all these bacteria in the pathogenesis and treatment of EC, and specifically high-grade histologies, requires further investigation.

The mechanisms by which the microbiome influences EC pathogenesis have yet to be determined but are likely multifactorial in the context of tumor stromal function and alterations in cancer cell signaling pathways. Lu et al recently reported that the presence of specific bacteria in the endometrium are associated with variable levels of the pro-inflammatory cytokines IL-6, IL-8, and IL-17 (34). These molecules are known to modify the local microenvironment, and have been implicated in gynecologic cancer development through increased angiogenesis, cellular proliferation, and modification of local immune response (35-37).

In patients with CRC, the presence of *F. nucleatum*, may activate the Wnt/β-catenin signaling pathway (38). In the endometrium, this pathway is important for normal physiologic cellular proliferation during the menstrual cycle, but oncogenic activation is also associated with EC development (39, 40). Consideration should also be given to environmental mediators of microbial content, as practices such as douching have also been shown to favorably modify the gynecologic tract for pathogens (41).

There are several limitations to our study. Our population was from a single institution, so the results may not be applicable in other study environments. Nonetheless, the population was racially and ethnically diverse, which may increase generalizability. Though our sample population was small, we were still able to identify statistically significant associations between CSTs and histology, with >90% power (Supplement 1). Additionally, these relationships were maintained across our analyses, including composition and differential abundance. We designed the study to specifically include more serous carcinoma patients, and this oversampling approach allowed for greater representation of understudied, high-risk endometrial histologies, relative to other reports (19, 20). Moreover these analyses used a metagenomics approach instead of 16S rRNA sequencing in the assessment of EC-associated microbiomes. This allowed for a more robust evaluation of relative microbial abundance and diversity. While others have advocated for the use of one or two species to discriminate between benign and malignant (19, 20), this study included multiple bacterial species to define clusters of organisms that collectively predicted not just malignancy, but subsets...
of disease. Such an approach can increase the accuracy of these models, especially as consideration is given to the clinical utility of the vaginal microbiome in disease assessment.

Conclusions

The vaginal microbiome reasonably segregates not only EC from benign disease, but also has strong potential predictive value by grade and histology. Further study in larger populations is needed to define its role as a biomarker in screening, early detection, and discernment between histologies as such data may directly drive changes in clinical decision-making. It will also be important to further characterize the relationships between the microbiome and tumor microenvironment, be they symbiotic or simply associative, and how these may contribute to disease etiology, tumor propagation, and potential novel therapeutic approaches.

Figure 1. Differential phyla abundance across benign, low-grade EC, and high-grade EC (p=0.093, across all three groups).
Figure 2. Differential abundance and CST structure. Differences were seen in the microbial phyla abundance by community state type (CST) (A). CSTs were also significantly associated with both tumor grade (B, p=0.036) and tumor histology (C, p=0.017) which ranged from EIN (endometrial intraepithelial neoplasia within the benign category) to endometrioid and rare HG-EC types like serous and carcinosarcoma.
**Figure 3. Differential abundance by tumor grade.** Positive fold change indicates enrichment of species, whereas negative fold change indicates paucity of species. In both HG and LG tumor vs benign, *Clostridium sp.* and *Porphyromonas uenonis* is more abundant (A). In HG vs benign states *Fusobacterium ulcerans* is the most abundant species (B). Similarly in HG vs LG endometrial cancers, *Fusobacterium ulcerans* and *Prevotella bivia* are the most abundant species (C). LG endometrial cancer metagenomes vs benign have distinct abundance of *Clostridium sp.*, *Corynebacterium amycolatum*, *Lactobacillus gasseri* and *Peptoniphilus duerdeni*, including *Porphyromonas uenonis* (D). Only taxa with significant changes in abundance are shown (adjusted p<0.05).
Figure 4. Biomarker Discovery by grade. Validation was performed on random forest classifier models, which identified an optimal microbiome signature for each cohort (A, C, E). These signatures were used to construct receiver operating curves which discriminate benign versus tumor (B), HG versus benign (D), and HG versus LG (F).
