Abstract

Background: Glucagon-like peptide-1 receptor (GLP1R) agonists decrease cardiovascular events in patients with type 2 diabetes, and cause weight loss regardless of diabetes status. The contribution of weight loss to the cardiovascular benefits of GLP1R agonists is unknown.

Methods: Obese pre-diabetic individuals were randomized to 14 weeks of the GLP1R agonist liraglutide, hypocaloric diet-mediated weight loss, or the dipeptidyl peptidase 4 inhibitor sitagliptin as an incretin-based drug comparator. Treatment with drug was double blind and placebo-controlled. Weight, metabolic and hemodynamic measures, endothelium-dependent vasodilation and fibrinolytic function were measured at baseline and after 2 and 14 weeks of treatment.

Results: Liraglutide and diet reduced weight, fasting blood glucose, and insulin resistance at 14 weeks, while sitagliptin did not. There was no significant effect of any treatment on endothelial vasodilatory function as measured by flow-mediated dilation (FMD). Because baseline endothelial function was normal in the overall cohort, post-hoc subgroup analyses were conducted in participants stratified by FMD below or above the median for gender. All three treatments improved FMD at 2 weeks in individuals with baseline endothelial dysfunction and sitagliptin and diet also improved endothelium-dependent vasodilation at 14 weeks. Liraglutide and diet reduced plasminogen activator inhibitor-1 (PAI-1) at 14 weeks. GLP1R antagonism with exendin (9-39) increased fasting blood glucose but did not change FMD or PAI-1 in the overall group. Exendin (9-39) attenuated the increase in FMD in the sitagliptin-treated group at two weeks.

Conclusions: Liraglutide and diet cause weight loss, improve insulin resistance and reduce PAI-1 at 14 weeks. The effect on PAI-1 is GLP1R-independent. In individuals with low baseline

FMD, sitagliptin and diet improve FMD at two and 14 weeks, while liraglutide improves FMD at two weeks.

Clinical Trial Registration: NCT03101930 https://clinicaltrials.gov/ct2/show/NCT03101930

Non-standard Abbreviations and Acronyms:

DPP4: Dipeptidyl peptidase 4

FMD: Flow-mediated dilation

GLP-1: Glucagon-like peptide-1

GLP1R: Glucagon-like peptide-1 receptor

GLS: Generalized least squares

HbA1c: Hemoglobin A1c

HOMA-IR: Homeostatic Model Assessment for Insulin Resistance

HOMA2: Homeostatic Model Assessment 2

NMD: Nitroglycerin-mediated dilation

OGTT: Oral glucose tolerance test

PAI-1: Plasminogen activator inhibitor-1

T2DM: Type 2 diabetes mellitus

UACR: Urine albumin-to-creatinine ratio

Introduction

Glucagon-like peptide-1 receptor (GLP1R) agonists decrease cardiovascular morbidity and mortality in patients with type 2 diabetes mellitus (T2DM).[1-3] GLP1R agonists also cause significant weight loss and have been approved as pharmacologic weight loss therapy.[4] Given that weight loss improves many of the risk factors for cardiovascular disease in patients with T2DM and insulin resistance,[5,6] weight loss might contribute to the beneficial cardiovascular effects of the GLP1R agonists.

Dipeptidyl peptidase 4 (DPP4) inhibitors increase endogenous GLP-1 without inducing weight loss. DPP4 inhibitors have not been shown to reduce cardiovascular mortality in T2DM.[7,8] In addition to preventing the degradation of GLP-1, DPP4 inhibitors also prevent the degradation and formation of a variety of vasoactive peptides, rendering their properties less specific.[9]

To understand the weight loss-independent effects of the GLP1R agonist liraglutide on vascular function, we compared the effects of the GLP1R agonist liraglutide to hypocaloric diet-induced weight loss and to treatment with the DPP4 inhibitor sitagliptin in a randomized controlled trial. We enrolled obese pre-diabetic individuals and measured weight, metabolic parameters, hemodynamic variables, endothelial function, and fibrinolysis after two weeks of therapy, before anticipated significant weight loss, and after 14 weeks of therapy. We evaluated endothelial function using flow-mediated vasodilation and assessed fibrinolysis by measuring plasminogen activator inhibitor-1 (PAI-1), the major inhibitor of tissue-type plasminogen activator *in vivo*. In addition, to assess whether the effects of treatment were GLP1R-dependent, we studied a subset of participants after treatment with the GLP1R antagonist exendin (9-39) and matching vehicle in a randomized, crossover design.

Methods

Participants

Men and women aged 18 to 65 years old with obesity (BMI $\geq$ 30 kg/m^2) and pre-diabetes were eligible for enrollment. Pre-diabetes was defined using the American Diabetes Association criteria as either impaired fasting glucose between 100-125 mg/dL or impaired glucose tolerance after a 75-gram glucose challenge of 140-199 mg/dL or hemoglobin A1c (HbA1C) 5.7-6.4%. Pregnancy was excluded in women of child-bearing potential by urine β-human chorionic gonadotropin testing. Individuals with type 1 or type 2 diabetes, resistant hypertension, history of pancreatitis, significant cardiovascular disease, asthma with regular inhaler use, and impaired kidney or liver function were excluded. The study was approved by the Vanderbilt Institutional Review Board, registered at clinicaltrials.gov NCT03101930, and conducted according to the Declaration of Helsinki. All participants provided written informed consent.

Protocol

Volunteers reported to the Vanderbilt Clinical Research Center to undergo screening. We obtained a medical history, completed a physical examination, and collected blood for measurement of HbA1C, complete blood count, basic metabolic panel, hepatic function panel, lipid profile, and collected urine for measurement of spot urine albumin-to-creatinine ratio (UACR). After an overnight fast, we performed a standard 75-gram oral glucose tolerance test with blood samples drawn at time 0, 30, 60, 90 and 120 minutes. We also measured resting energy expenditure (REE).

Eligible participants who chose to continue with the study underwent a six-week run-in

phase to optimize their medical management (**Supplemental Figure 1A** and detailed methods in **Supplemental Materials**). After the run-in phase, participants underwent a baseline study day during which we made anthropometric and hemodynamic measurements, measured flow-mediated dilation (FMD), collected blood for measurement of glucose, insulin, PAI-1, and P-selectin (platelet function), collected urine for albumin and creatinine, and performed a mixed-meal study.

Participants were then randomized to liraglutide 1.8mg/day (Novo Nordisk), sitagliptin 100mg/day (Merck and Co, Inc), or hypocaloric diet in a 2:1:1 ratio, stratified by race. Liraglutide was given on a dose escalation starting at 0.6mg/day for week 1, 1.2mg/day for week 2 and then up to the full dose of 1.8mg/day at the start of week 3. Treatment with liraglutide or sitagliptin was double blind and placebo-controlled, while treatment with diet was unblinded. Study drugs and placebo were a generous gift from Novo Nordisk.

Participants were treated for a total of 14 weeks. The first 74 participants underwent four study days. The first two study days were conducted after two weeks of treatment to measure the short-term effects of liraglutide, sitagliptin and diet. The first and second study days were separated by 48 hours and participants received a single dose infusion of placebo or the GLP1R antagonist exendin (9-39) on each day in random order to assess the contribution of GLP1R activation to any observed effects. The third and fourth study days were completed after 14 weeks to measure the effects of sustained liraglutide, sitagliptin and weight loss. The third and fourth study days were also separated by 48 hours and participants again received placebo or exendin (9-39) infusion in random order. The last 14 participants studied did not participate in the crossover aim with exendin (9-39) due to lack of drug availability, and only underwent two study days, one after two weeks of treatment and one after fourteen weeks of treatment. Placebo

vehicle was infused during each of these study days. All participants underwent repeat REE measurement and urine collection after 13.5 weeks of treatment at a separate visit to the Clinical Research Center.

Study Day Protocol

Participants randomized to drug were called the night prior to each study day to ensure they had taken their subcutaneous injection. On the morning of each study day, participants arrived at the Clinical Research Center after an overnight fast. Those randomized to drug took their oral medication upon arrival (**Supplemental Figure 1B**). Participants then rested supine for 45 minutes, and we measured blood pressure and heart rate and collected blood for measurement of PAI-1 and P-selectin. After this rest period, participants were given placebo or the GLP1R antagonist exendin-(9-39) (Clinalfa®, Bachem Distribution Services; Weil am Rhein, Germany; IND #122,217) in randomized order on study days 1 and 2, and on study days 3 and 4. Exendin-(9-39) was given as an IV bolus of 7500 pmol/kg over one minute followed by continuous infusion of 350 pmol/kg/min for the remainder of the study. Infusion with placebo or exendin-(9-39) was double blind.

An hour after the start of the infusion, we measured FMD, then collected blood for measurement of PAI-1 and P-selectin, as well as fasting glucose and insulin. We then administered sublingual nitroglycerin 0.4mg for measurement of nitroglycerin-mediated vasodilation (NMD). After the FMD/NMD and approximately three hours following administration of oral study drug and 2 hours after start of infusion, participants ingested a standardized mixed-meal.

<u>Measurement of Flow-Mediated Dilation</u>

Measurement of endothelium-dependent and endothelium-independent vasodilation was performed in a quiet, temperature-controlled (23°C) room. Participants were asked to refrain from alcohol and caffeine for at least 12 hours prior to vascular function measurements. In addition, participants were asked to abstain from phosphodiesterase type 5 inhibitors for at least one week as these drugs may confound the measurement of vascular function or cause precipitous hypotension after nitroglycerin. Premenopausal women were studied during the same phase of the menstrual cycle at each visit to avoid variability of vascular function measures. FMD and NMD were measured as reported previously and detailed in **Supplemental Materials**.[10-13]

<u>Hypocaloric Diet</u>

Participants in the hypocaloric diet arm were given a caloric goal designed to achieve a weight loss similar to that expected in the liraglutide treatment arm; based on prior studies of 1.8 mg/d liraglutide this was predicted to be ~0.27 kg/week.[14-17] Each participant's caloric goal was determined by measuring REE at baseline and calculated to reduce total energy balance by 390 kcal/d.[18] Participants were provided counseling and written instructions on how to achieve their daily caloric goal, including use of their own mobile phone applications to monitor caloric intake. To assure compliance with the prescribed caloric goal, participants met with the study dietitian every other week for problem solving and review of diet intake logs.

REE was measured in the supine position using a Parvo TrueOne 2400 portable metabolic system (ParvoMedics, Sandy, Utah) in a dimly lit, temperature-controlled room. A ventilated plexiglass hood was placed over the participant's head and connected to the metabolic

cart by a single expired-gas hose. Indirect calorimetry was measured for 25-30 min, with the first 5-10 min eliminated from analysis. Before each use, the system was calibrated using room air and a single gas tank (~16% O_2, 1% CO_2). Whole-body rates of O_2 consumption and CO_2 production were determined from measurements of expired volume, and the differences in O_2 and CO_2 concentration between inspired and expired air. Ventilation was measured by a mass flow meter, oxygen concentration by a paramagnetic O_2 analyzer, and CO_2 by an infrared analyzer. REE was calculated from the Weir equation.[19]

Dietary recalls were performed by trained registered dietitians using the validated U.S.D.A. multi-pass recall method, a standardized script and software generated prompts. Intakes was analyzed for energy and nutrient content via Nutrition Data System (NDSR version 2016, U Minn) which automatically calculates average energy, macronutrients, micronutrients, nutrient ratios, food components and indices.

Laboratory Analyses

A YSI glucose analyzer (YSI Life Sciences, Yellow Springs, OH) was used to measure plasma glucose immediately after collection. All remaining samples were stored at -80°C in aliquots until the time of assay. Plasma insulin samples were collected in tubes containing aprotinin, and insulin was measured by radioimmunoassay (EMD Millipore, Billerica, MA). The assay cross-reacts with 38% intact proinsulin, but not with C-peptide ($\leq 0.01\%$). Blood for PAI-1 was collected in 0.105 M acidified sodium citrate and samples were analyzed using commercially available two-site ELISA using chromogenic substrates (TriniLIZE, Trinity Biotech, Berkeley Heights, NJ and American Diagnostica Inc, Stamford, CT). Serum samples for p-selectin were collected in a BD red top vacutainer tube, incubated at room temperature for 30

minutes, spun at 2,000 RPM for 10 minutes, then aliquoted for storage at -80C until measured by

ELISA (R&D Systems, Minneapolis, MN). Creatinine was measured using the Jaffe method.

Urine albumin was measured by turbidimetric immunoassay with endpoint determination.

HbA1C was measured using high pressure liquid chromatography (HPLC).

Statistical Analyses

The primary endpoints were endothelial vascular function (FMD, UACR), and PAI-1, a

marker of endothelial fibrinolytic function. Secondary endpoints reported here include blood

pressure, heart rate, fasting insulin and glucose, and P-selectin as a marker of platelet function.

Descriptive statistics of patient baseline characteristics were presented as mean ± SD for

continuous variables and frequencies and proportions for categorical variables. Between-group

comparison was performed using Kruskal–Wallis test or Pearson's chi-squared test. Within-

subject change in the endpoints at 2- and 14-week from baseline in each treatment group was

tested using paired t-test. To evaluate the treatment effects on weight, fasting blood glucose,

systolic blood pressure, diastolic blood pressure, heart rate and pre-infusion PAI-1 and P-

selectin, separate multivariable generalized least squares (GLS) linear regression models were

fitted using the data from vehicle-only study days. Treatment (liraglutide, sitagliptin or diet),

time (2- or 14-week), baseline measurement as well as interaction between treatment and time

were included as independent variables. A compound symmetry structure for within-subject

correlation was used. For fasting blood glucose, fasting insulin, Homeostatic Model Assessment

for Insulin Resistance (HOMA-IR), FMD percent and post-infusion PAI-1, GLS models were

fitted using data from all study days. Treatment (liraglutide, sitagliptin or diet), infusion (vehicle

or exendin (9-39)), time (2- or 14-week), baseline measurement as well as all the two-way and

three-way interactions between treatment, time and infusion were included as independent variables. Inferences on the contrasts of interest was conducted using Wald test. All the analyses were performed using the statistical software R 4.1.0.[20]

We powered our study based on anticipated improvement in endothelial function. In studies of weight loss, improvement in endothelial function is proportionate to weight loss and the degree of weight loss achieved with liraglutide in the LEADER study has been associated with a 1.3%±2.1% increase in brachial artery FMD.[21] To detect a difference of 1.3%±2.1% for within-individual comparisons, we had 79% power in the diet and sitagliptin arms (N=22), and 98% power in the liraglutide arm (N=44).

Results

Participant characteristics

Ninety-three individuals were randomized to treatment, with 46 to liraglutide, 23 to sitagliptin, and 24 to hypocaloric diet (**Supplemental Figure 2**). Three participants dropped out prior to receiving treatment, and two dropped out after receiving treatment but before completing any study days. Data from the remaining 88 individuals (44 randomized to liraglutide, 22 to sitagliptin, and 22 to hypocaloric diet) were analyzed. Seven individuals dropped out after completing study days 1 and 2 (two randomized to liraglutide, five to diet) and their available data were included in the analyses. **Table 1** shows characteristics of the participants by treatment arm.

Effect of treatment on weight and metabolic measures

Liraglutide and diet caused weight loss, while sitagliptin did not (**Figure 1A** and **Table**

2). Individuals in the diet arm lost significant weight from baseline at both 2 and 14 weeks (2 weeks: difference -1.4 kg, 95% CI [-2.2, -0.6], P<0.01; 14 weeks: -5.0 kg [-7.0, -2.9], P<0.001). Individuals in the liraglutide arm lost a small amount of weight from baseline to 2 weeks (-0.5 kg [-0.99, 0.01], P=0.05), and continued to lose weight by 14 weeks (-2.7 kg [-3.8, -1.7], P<0.001). Hypocaloric diet-treated participants lost more weight compared to liraglutide-treated participants at 14 weeks (-2.3 kg [-3.7, -0.9], P<0.01). In addition, both diet-treated and liraglutide-treated participants lost more weight than sitagliptin-treated participants at 14 weeks (liraglutide vs sitagliptin -2.0 kg [-3.3, -0.6], P<0.01; diet vs sitagliptin -4.2 kg [-5.8, -2.6], P<0.001).

Liraglutide and diet decreased HOMA-IR, a measure of insulin resistance, while sitagliptin did not (**Figure 1B** and **Table 2**). Diet caused the greatest decrease in HOMA-IR at both 2 and 14 weeks compared to baseline (2 weeks: -1.9 [-3.2, -0.6], P<0.01; 14 weeks: -2.3 [-3.9, -0.6], P=0.01). Liraglutide also decreased HOMA-IR at both 2 and 14 weeks (2 weeks: -1.3 [-2.2, -0.3], P=0.01; 14 weeks: -1.2 [-2.0, -0.3], P=0.01). Both diet-treated and liraglutide-treated participants had a greater decrease in HOMA-IR than sitagliptin-treated participants at 14 weeks (liraglutide vs sitagliptin -1.6 [-3.1, -0.1], P = 0.03; diet vs sitagliptin -2.3 [-4.1, -0.5], P=0.01).

As shown in **Figure 1C** and **Table 2**, liraglutide and diet decreased fasting blood glucose, while sitagliptin did not. Liraglutide caused an early and sustained decrease in fasting blood glucose from baseline (2 weeks: -10.8 mg/dL [-14.0, -7.7], P<0.001; 14 weeks: -10.2 mg/dL [-13.3, -7.2], P<0.001). Hypocaloric diet caused a small but significant decrease in fasting blood glucose by 14 weeks (2 weeks: -2.1 mg/dL [-5.6, 1.3], P=0.22; 14 weeks: -3.0 mg/dL [-5.9, -0.1], P=0.04). Sitagliptin did not significantly alter fasting blood glucose at 2 or 14 weeks (2 weeks: -3.5 mg/dL [-6.9, 0.01], P=0.05; 14 weeks: -1.7 mg/dL [-5.2, 1.8], P=0.32). Liraglutide caused the

greatest reduction in fasting glucose at 14 weeks (liraglutide vs sitagliptin -9.2 mg/dL [-13.9, -4.5], P<0.001; liraglutide vs diet -6.9 mg/dL [-11.9, -2.0], P<0.01).

Finally, as shown in **Figure 1D** and **Table 2**, diet decreased fasting insulin at both 2 and 14 weeks compared to baseline (2 weeks: -7.0 µU/mL [-11.7, -2.2], P<0.01; 14 weeks: -7.5 µU/mL [-13.0, -2.0], P=0.01). Liraglutide tended to decrease fasting insulin, although this did not reach statistical significance (2 weeks: -3.9 µU/mL [-8.0, 0.2], P=0.06; 14 weeks: -3.1 µU/mL [-7.0, 0.9], P=0.12). Sitagliptin did not alter fasting insulin at 2 or 14 weeks.

Effect of treatment on resting hemodynamics

Systolic blood pressure decreased significantly after hypocaloric diet (2 weeks: -6.1 mmHg [-9.5, -2.6], P<0.01; 14 weeks: -8.1 mmHg [-13.8, -2.5], P<0.01), but not with liraglutide or sitagliptin (**Figure 2A**). Diastolic blood pressure also decreased significantly after 14 weeks of hypocaloric diet (-3.8 mmHg [-7.4, -0.2], P=0.04) (**Figure 2B**). Liraglutide treatment increased heart rate at both 2 weeks (+4.0 bpm [2.3, 5.8], P<0.001) and 14 weeks (+3.7 bpm [1.5, 5.9], P<0.01; **Figure 2C**).

Effect of treatment on endothelial vasodilatory function

Baseline brachial artery diameter and FMD percent were comparable among treatment groups (**Figure 3A** and **Table 2**). Both liraglutide and sitagliptin tended to increase FMD as compared to baseline, however this increase did not reach statistical significance for either drug alone (Liraglutide 2 weeks: +0.7% [-0.9, 2.3], P=0.36; 14 weeks: +1.4% [-0.3, 3.1], P=0.10; Sitagliptin 2 weeks: +2.1% [-0.9, 5.1], P=0.17; 14 weeks: +1.6% [-1.0, 4.1], P=0.21). There was neither effect nor trend for hypocaloric diet on FMD at either 2 (+1.2% [-1.1, 3.6], P=0.28) or 14

weeks (+1.0% [-1.9, 3.9], P=0.46). There was no significant change in endothelium-independent NMD in any of the treatment groups (**Table 2**).

In considering the cohort's clinical characteristics, we noted that baseline endothelial function was similar to our past work in healthy subjects.[12,22] In a post-hoc exploratory analysis, we divided the cohort into those with baseline FMD below or above the median for gender, to query the effect of treatment in individuals with normal and reduced baseline endothelial function. Baseline characteristics of these subgroups are shown in **Table 3**. Three individuals were missing baseline FMD and were excluded from this analysis. Individuals with lower baseline FMD had increased BMI, waist circumference, fasting insulin and insulin resistance as measured by HOMA-IR and HOMA2 compared to those with higher baseline FMD. As shown in **Figure 3B**, in individuals with lower baseline FMD, treatment with liraglutide, sitagliptin and hypocaloric diet improved FMD after 2 weeks. This effect remained significant in the sitagliptin and diet groups at 14 weeks. Of note, FMD in individuals with normal baseline FMD did not change with any intervention (**Figure 3C**).

Urine albumin-to-creatinine ratio, which is associated with vascular endothelial function and is a predictor of cardiovascular events,[23-25] was not changed by treatment (**Table 2**).

Effect of treatment on fibrinolysis

We evaluated endothelial fibrinolytic balance by measuring PAI-1 concentration. Liraglutide and hypocaloric diet significantly decreased PAI-1 concentration from baseline to 14 weeks of treatment (liraglutide: -3.7 U/mL [-6.5, -1.0], P<0.01; diet: -3.6 U/mL [-7.1, -0.1], P<0.05; **Figure 4**) but not at 2 weeks. Sitagliptin treatment did not affect PAI-1 concentration. In addition, PAI-1 levels were lower at 14 weeks in both the liraglutide- and diet-treated individuals

compared to sitagliptin (liraglutide vs sitagliptin: -3.7 U/mL [-6.7, -0.6], P=0.02; diet vs

sitagliptin: -4.8 U/mL [-8.5, -1.1], P=0.01). P-selectin, a marker of platelet and endothelial

activation, was unchanged by treatment (**Table 2**).

Effect of GLP1R antagonism

To test the hypothesis that GLP1R activation contributes to the acute or sustained effects

of liraglutide or sitagliptin, we compared the effect of pretreatment with the GLP1R antagonist

exendin (9-39) and vehicle on effects of treatment at 2 and 14 weeks. As shown in **Figure 5A,**

GLP1R antagonism with exendin (9-39) raised fasting blood glucose in all treatment groups at

both 2 and 14 weeks. Overall, exendin did not change FMD in liraglutide, sitagliptin, or diet-

treated participants (**Figure 5B**). In the stratified analysis of those with below-median FMD,

exendin decreased FMD in sitagliptin-treated individuals at 2 weeks (-3.6 [-6.8, -0.4], P=0.03),

but not at 14 weeks (-0.4 [-3.6, 2.8], P=0.82) as compared to vehicle. Finally, there was no effect

of GLP1R antagonism on PAI-1 concentrations in any treatment group (data not shown).

Discussion

GLP1R agonists reduce major adverse cardiovascular outcomes in T2DM and cause

weight loss in obese individuals. We performed a randomized controlled study comparing the

effects of treatment with a GLP1R agonist, hypocaloric diet-induced weight loss, and a DPP4

inhibitor in obese pre-diabetic individuals. Our aim was to dissect the weight loss-dependent and

-independent effects of GLP1R agonist treatment on intermediate measures of cardiovascular

disease. We found no effect of liraglutide, diet-induced weight loss, or sitagliptin on

endothelium-dependent vasodilation as measured by FMD in the overall cohort. In a post-hoc

exploratory analysis, liraglutide, weight loss, and sitagliptin all improved endothelial function in those individuals with baseline FMD below the median of our cohort after 2 weeks, and this effect remained significant in the sitagliptin and weight loss groups at 14 weeks. In contrast, liraglutide treatment and weight loss, but not sitagliptin treatment, significantly reduced PAI-1 after 14 weeks, and GLP1R antagonism did not alter this effect.

Prior studies of the effects of GLP1R agonists on endothelial function as measured by FMD were all performed in individuals with T2DM and demonstrated mixed results. Two studies found no effect,[26,27] three reported improvement in FMD,[28-30] and a systematic review and meta-analysis did not find a significant effect of GLP1R agonists on FMD. Interpretation of these data are limited by the modest number of and heterogeneity between published studies.[31] Our study is the largest evaluating the effect of GLP1R agonist treatment on FMD to date, and the first study that is controlled and blinded (to drug assignment). Notably, our overall cohort demonstrated intact endothelium-dependent vasodilation compared to participants in prior studies, with a median FMD 9.91% compared to values ranging from 1.6-8.9% in prior studies. We anticipated FMD to be better in individuals with pre-diabetes as compared to those with type 2 diabetes at the outset. However, our recruitment created a group with FMD similar to a healthy group, not one with pre-diabetes.[12] Our exploratory analysis supports the hypothesis that liraglutide may improve FMD in obese individuals with prediabetes and attenuated baseline FMD. This work also shows that improvements beyond normal do not occur, as we have shown previously.[32]

We assessed the on-target effects of GLP1R activation by measuring the impact of co-treatment with the GLP1R antagonist exendin (9-39). GLP1R inhibition significantly increased fasting glucose at 2 and 14 weeks in all treatment groups. This effect of exendin on fasting

glucose has been demonstrated previously.[33,34] GLP1R antagonism did not change FMD percent or PAI-1 measurements in the overall cohort. Exendin attenuated FMD after 2 weeks of treatment with sitagliptin in the subgroup of individuals with lower baseline endothelial function, suggesting that increased endogenous GLP-1 contributed to improved endothelium-dependent vasodilation during early sitagliptin treatment in this group.

PAI-1 is the primary inhibitor of tissue plasminogen activator and is central to regulating fibrinolysis. PAI-1 is increased in obese[35] and insulin resistant individuals,[36-38] and PAI-1 levels predict incident myocardial infarction.[39] PAI-1 expression is upregulated by inflammatory stimuli such as interleukin-6 and tumor necrosis factor-alpha, as well as by metabolic stimuli including hyperglycemia, hyperinsulinemia, and elevated VLDL.[38] PAI-1 has been found to decrease after weight loss[40] or treatment with GLP1R agonists.[41,42] Three pieces of evidence suggest that improvements in PAI-1 are mediated by reductions in weight and coincident improvements in dysmetabolism. First, PAI-1 decreased with both liraglutide treatment and hypocaloric diet only after clinically significant weight loss at 14 weeks. Second, HOMA-IR decreased in these two groups, but not in the sitagliptin-treated group. Third, exendin (9-39), a GLP1R antagonist, had no effect on PAI-1. These data support the notion that the decrease in PAI-1 after GLP1R agonist treatment is mediated by weight loss and improvement in insulin resistance, rather than a receptor-specific effect.

Weight loss in the hypocaloric diet group was associated with a significant decline in systolic blood pressure over 14 weeks, whereas there was no decrease in systolic blood pressure in either the sitagliptin or liraglutide group. Weight loss was significantly less in the liraglutide-treated group compared to in the hypocaloric diet-treated, and stimulation of the sympathetic nervous system may have counteracted any favorable effect of weight loss on systolic blood

pressure in the liraglutide-treated group. Activation of GLP-1 receptors in the hypothalamus and brainstem by long-acting GLP1R agonists stimulate sympathetic outflow.[43] Increased heart rate, observed in the liraglutide-treated group, is a hallmark of treatment with stable GLP1R agonists.[44] Interestingly, treatment with sitagliptin did not increase heart rate. We have previously reported that heart rate is increased after short-term treatment with sitagliptin and ACE inhibition,[45,46] but not after longer duration treatment,[47] even though norepinephrine concentrations are increased. Decreased degradation of substance P may contribute to sympathetic stimulation when both DPP4 and ACE are inhibited. In the present study, a minority of participants were taking concurrent anti-hypertensive medications.

This study has several limitations. The majority of participants enrolled were women. The study was not powered to permit comparison between effects in men and women. In addition, we enrolled individuals with pre-diabetes rather than overt diabetes, which may have diminished the effect size of our treatment by eliminating the hyperglycemia component of vascular dysfunction.[48] We chose to study obese pre-diabetic individuals to study a homogenous population with baseline insulin resistance but without overt hyperglycemia so as to avoid confounding by concurrent anti-diabetic medications or by varying severity and duration of diabetes. As noted, the participants had normal baseline endothelium-dependent vasodilation. We completed a post-hoc analysis stratified by baseline FMD below and above the median. Although not pre-specified, the finding that those with lower baseline FMD were significantly more insulin resistant than those with higher baseline FMD provides physiologic support of the analysis.

In conclusion, in the largest study of the effect of a GLP1R agonist on brachial artery endothelium-dependent vasodilation, liraglutide, sitagliptin, and weight loss had no effect in

obese pre-diabetic individuals with normal baseline endothelial function. Liraglutide and sitagliptin both improved FMD in those individuals with below-median FMD and the effect of sitagliptin was attenuated by a GLP1R antagonist at 2 weeks. Weight loss, whether due to liraglutide therapy or hypocaloric diet, decreased PAI-1 through a GLP1R-independent mechanism. Future studies exploring alternate mechanisms for the cardiovascular benefits of GLP1R agonists, such as reductions in vascular inflammation, are needed.[49]

FMD, %	**6.55±2.81****	14.39±3.94	10.42±5.20

All measures shown as mean±SD for continuous variables and % (N) for categorical variables. OGTT indicates oral glucose tolerance test; HOMA-IR, Homeostatic Model Assessment for Insulin Resistance; HOMA2, Homeostatic Model Assessment 2; FMD, flow-mediated dilation. * $P<0.05$ and ** $P<0.001$ versus FMD% greater than median.

Figure 1

Figure 1. The Effect of Treatment on Weight, Fasting Blood Glucose, Fasting Insulin, and Insulin Resistance. Plots show mean ± SEM for **(A)** weight, **(B)** fasting blood glucose, **(C)** fasting insulin, and **(D)** HOMA-IR at 2 and 14 weeks of treatment as change from baseline. Asterisks indicate P<0.05 for the change from baseline. Brackets indicate difference between

treatments at 14 weeks in regression model. HOMA-IR indicates Homeostatic Model

Assessment of Insulin Resistance.

Figure 2

Figure 2. The Effect of Treatment on Hemodynamic Measures. Plots show mean ± SEM for **(A)** systolic blood pressure, **(B)** diastolic blood pressure, and **(C)** heart rate at 2 and 14 weeks of treatment as change from baseline. Asterisks indicate P<0.05 for the change from baseline. Brackets indicate difference between treatments at 14 weeks in regression model.

Figure 3

Figure 3. The Effect of Treatment on Flow-Mediated Dilation. Plots show mean ± SEM for **(A)** FMD percent in entire cohort,

(B+C) FMD percent in subgroups of individuals with baseline FMD **(B)** below median or **(C)** above median for gender. Asterisks

indicate P<0.05 for the change from baseline. Brackets indicate difference between treatments at 14 weeks in regression model with

gender as a covariate. FMD indicates flow-mediated dilation.

Figure 4

Figure 4. The Effect of Treatment on PAI-1. Plot shows mean ± SEM for PAI-1 at 2 and 14 weeks of treatment as change from

baseline. Asterisks indicate P<0.05 for the change from baseline. Brackets indicate difference between treatments at 14 weeks in

regression model. PAI-1 indicates plasminogen activator inhibitor-1.

Figure 5

Figure 5. The Effect of the GLP1R Antagonist Exendin (9-39) on Fasting Blood Glucose and FMD. Plots show mean ± SEM for

(A) fasting blood glucose and **(B-D)** FMD percent. **(A)** Fasting blood glucose at 2 and 14 weeks of treatment as change from baseline.

(B) FMD percent in the entire cohorts; **(C)** in subgroup with baseline FMD percent below median; **(D)** in subgroup with baseline

FMD above median. Symbols (†) indicate $P<0.05$ exendin versus vehicle in regression model. GLP1R indicated glucagon-like

peptide-1 receptor. FMD indicates flow-mediated dilation.
