11 **potential, machine learning**

12 Abstract

13 Antecedent: The diagnosis of schizophrenia could be enhanced with objective neurophysiological
14 biomarkers, such as the event related potential features in conjunction with machine learning
15 procedures. A previous work extracted features from event related responses to three oddball
16 paradigms (auditory and visual P300, and mismatch negativity) for the discrimination of schizophrenic
17 patients. They used several classifiers: Naïve Bayes, Support Vector Machine, Decision Tree,
18 Adaboost and Random Forest. The best accuracy was obtained with Random Forest (84.7%).

19 Objective: The aim of this study was to examine the efficacy of Multiple Kernel Learning classifiers
20 and Boruta feature selection method exploring different features for single-subject classification
21 between schizophrenia patients and healthy controls.

22 Methods: A cohort of 54 schizophrenic subjects and 54 healthy control subjects were studied. Three
23 sets of features related to the event related potentials signal were calculated: Peak related features, Peak
24 to Peak related features and Signal related features. The Boruta feature selection algorithm was used
25 to evaluate its impact on classification accuracy. A Multiple Kernel Learning algorithm was applied to
26 address schizophrenia detection.

27 Results: We obtained a classification accuracy of 83% using Multiple Kernel Learning classifier with
28 the whole dataset. This result in accuracy triangulates previous work and shows that the differences
29 between schizophrenic patients and controls are robust even when different classifiers are used.
30 Applying the Boruta feature selection algorithm a classification accuracy of 86% was yielded. The
31 variables that contributed most to the classification were mainly related to the latency and amplitude
32 of the auditory P300.

33 Conclusion: This study showed that Multiple Kernel Learning can be useful in distinguishing between
34 schizophrenic patients and controls. Moreover, the combination with the Boruta algorithm provides an
35 improvement in classification accuracy and computational cost.

36

37 **1 Introduction**

38 Schizophrenia is a severe and persistent debilitating psychiatric disorder with prevalence of 1% of the
39 world population (McGrath et al., 2004). Although psychotic symptoms such as hallucinations and
40 delusions are frequently present, impaired information processing is probably the most common
41 symptom (Javitt et al., 1993). This deficit is reflected mainly in deficits in attention and working
42 memory tasks when compared with healthy controls (Li et al., 2018). The diagnosis of schizophrenia
43 is made by psychiatrists by ascertaining the presence of predefined symptoms (or their precursors)
44 with personal interviews. However, in some cases this diagnosis is unclear, or patients are
45 misdiagnosed with Schizophrenia (Coulter et al., 2019). Thus, finding biomarkers for the prediction
46 of individuals with schizophrenia would be desirable in order to choose the optimal treatment
47 (pharmacologic or non-pharmacologic). Analysis of EEG recording during information processing
48 tasks could provide objective complimentary measures to support the subjective human-based
49 decision process (Sabeti et al., 2009; Koukkou et al., 2018) .

50 EEG is a non-invasive and low-cost technique used to measure electrical brain activity along multiple
51 scalp locations. EEG signals have been widely adopted to study mental disorders, such as dementia,
52 epileptic seizures, cognitive dysfunction, among others, as well as schizophrenia (Loo et al., 2016;
53 Olbrich et al., 2016; Horvath et al., 2018). EEG reflects the spontaneous activity of myriad brain
54 parcels, but also can include responses to afferent stimuli (Cong et al., 2015). Event related potentials
55 (ERPs) are electrical responses that are time-locked to a specific stimulus or event, and can be used
56 to assess brain dynamics during information processing in specific tasks (Woodman, 2010). When a
57 subject is presented with a series of standard stimuli, interspersed with infrequent deviant stimuli, the
58 Mismatch Negativity (MMN) (Lee et al., 2017) and the P300 (Li et al., 2018) components are
59 generated. This task is known as the oddball paradigm and is used to study schizophrenia since
60 consistent deficits in the P300 and MNN have been reported in this disease (Bramon et al., 2004;
61 Javitt et al., 2017). Although MMN and P300 are usually produced by an infrequent unexpected
62 event in a sequence of auditory stimuli, P300 can also be obtained with visual stimuli. The MMN is
63 of shorter latency and does not require attention to the stimulus (Näätänen et al., 2004), whereas the
64 P300 is of longer latency and requires attention to the stimulus (Huang et al., 2015).

65 Several studies have reported significant differences in the latency and amplitude of MMN and P300
66 between controls and patients, suggesting that these features are possible markers of the prodromal
67 phase of schizophrenia (Atkinson et al., 2012; Loo et al., 2016) as well as a potential endophenotypes
68 for schizophrenia (Earls et al., 2016). Analysis of a large dataset of auditory P300 ERP (649 controls
69 and 587 patients) confirmed the reliability of this reduced amplitude, with a large effect size
70 (Turetsky et al., 2015). However, these findings of statistically significant differences in a group
71 analysis does not imply that EEG is useful for the prediction of individual schizophrenia cases (Lo et
72 al., 2015), which requires applying a prediction paradigm using Machine Learning.

73 Accordingly, machine learning techniques are being applied to classify between schizophrenics (SZs)
74 and healthy controls (HCs) using ERPs. The most common features used are based on amplitude and
75 latency of different components (e. g. N100 and P300 (Neuhaus et al., 2013), P50 and N100 (Iyer et
76 al., 2012; Neuhaus et al., 2014)), with several classifiers tested. Neuhaus et al. using visual and

77 auditory oddball paradigms and a k-nearest neighbor (KNN) classifier obtained a classification
78 accuracy of 72.4 % (Neuhaus et al., 2013). The same author with a bigger sample size and a Naive
79 Bayes (NB) classifier achieved a 77.7% of accuracy (Iyer et al., 2012). Laton et al. evaluated the
80 performance of several classifiers extracting features from auditory/visual P300 and MMN (Laton et
81 al., 2014). The results using NB and Decision Tree (without and with AdaBoost) achieved accuracies
82 of about 80%. Recently, Barros et al. published a critical review that summarizes machine learning-
83 based classification studies to detect SZs based on EEG signals, conducted since 2016, (Barros et al.,
84 2021). These authors reported that Support Vector Machines (SVM) were the commonly used
85 algorithms, probably due to its computational efficiency. This kernel-based learning method also
86 achieved the best performance in most studies. Nevertheless, none of the studies focused on ERPs,
87 have used multiple kernels, employing instead only one specific kernel function.

88 The multiple kernel learning (MKL) method learns a weighted combination of different kernel
89 functions and is able to benefit from information coming from multiple sources (Wani and Raza,
90 2018). It has been used to address the problem of biomarker evaluation for schizophrenia detection,
91 but basically applied to Magnetic Resonance Images increasing performance accuracy (Ulaş et al.,
92 2012; Castro et al., 2014; Liu et al., 2017). However, as far as we know, application of MKL to
93 electrophysiological data has been not explored for schizophrenia, even though some authors are
94 applying this technique to EEG signals for other purposes, mainly brain computer interfaces (Li et
95 al., 2014; Zhang et al., 2017). Thus, MKL has not been applied in the objective diagnosis of
96 Schizophrenia using EEG.

97 Here, using the same dataset provided by Laton et al. (Laton et al., 2014), we extended the set of
98 predictor variables beyond the latency and amplitude of the ERP components, by including additional
99 morphological features (based on time) together with some features extracted from the frequency
100 domain. Due to the large number of features, the Boruta method was applied, which is a wrapper
101 Random Forest (RF) based feature selection algorithm, to estimate the impact of a subset of
102 important and relevant feature variables in the classification accuracy. The multiple kernel learning
103 (MKL) was evaluated for the classification of SZs versus HCs.

104 **2 Materials and methods**

105 **2.1 Dataset**

106 The study was carried out on data from 54 patients and 54 controls, matched for age and gender.
107 Patients were classified by a semi-structured interview (OPCRIT v4.0) and all participants gave written
108 informed consent. Detailed demographic data can be found in **Table 1**. EEGs were recorded using a
109 64-channel and the international 10/10 system, with a sampling frequency of 256 Hz. Three paradigms
110 auditory/visual P300 and MMN were used. **Table 2** shows a brief description of paradigms.

111 The signals were filtered using bandpass Butterworth filters with cutoffs at 0.1 and 30 Hz. Epochs
112 were extracted using time windows between -200 and 800 ms for the P300 paradigms, and between -
113 100 and 500 ms for the MMN. Subsequently, baseline correction, re-referencing to linked ears and
114 artefact rejection were performed. Finally, epochs were averaged into stimulus specific responses for
115 each individual and low-pass filter and baseline correction were re-applied. More details can be found
116 in Laton et al (Laton et al., 2014).

117 **2.2 Feature extraction**

118 Feature extraction has been carried out on the waveform of ERPs emerged as the averaging of the
119 electrical responses corresponding to the set of stimuli different from the standard stimulus (Target
120 and Distractor for P300, Duration and Deviant for MNN). Only Fz, Cz and Pz channels were
121 considered (see **Figure 1**). Thus, the number of features extracted for classification purposes was 726
122 (282 features for each P300 paradigms and 162 for MMN paradigm). The feature values were
123 standardized to ensure that all of them have equal weight during training of the classifiers. These
124 standardized values were then normalized, rescaling them all to values between 0 and 1. In this
125 binary classification problem, patients and controls were 1 and 0 respectively.
126 The set of features can be divided into three categories: Peak related features, Peak to Peak related
127 features and Signal related features. Details about feature definitions are presented in **Annex 1**. Some
128 of these features were previously used for other authors to calculate features related to the ERP signal
129 (Kalatzis et al., 2004; Abootalebi et al., 2009). Four peaks for P300 paradigms (N100, P200, N200,
130 and P300) and two peaks for MMN paradigm (N200, P300) were considered (see **Figure 2**).

131 **2.2.1 Peak related features**

132 Peaks were estimated using the same algorithm described in Laton et al (Laton et al., 2014). The
133 algorithm detects the largest absolute value in an interval established around the average latency of
134 the peak in the respective grand average. This value is considered as *Amplitude* of the corresponding
135 peak, their *Latency* is the time where the peak appears in the respective time interval. To ensure little
136 overlap between the intervals, the detection interval was extended to contain the latency of peak most
137 deviated. To search the latency of the peak, the minimum value of the corresponding detection
138 interval was changed by the latency of the previous searched peak to avoid mistakes in the order of
139 the ERPs components. The other features were: *Absolute Amplitude*, *Latency/Amplitude ratio*,
140 *Absolute Latency/Amplitude ratio*, *Average Absolute Signal Slope* and *Slope sign alterations*.

141 **2.2.2 Peak to Peak related features**

142 Three features were calculated considering the relationship between adjacent selected peaks: the
143 absolute difference between the amplitude of the peak and the next peak in latency order; the
144 difference in latencies of these two peaks; and the slope of the signal in this time window.

145 **2.2.3 Signal related features**

146 Features considering the area under the curve were calculated: the sum of the positive signal values
147 (*Positive Area*); the sum of the negative signal values (*Negative Area*); the *Total Area*, and *Absolute*
148 *Total Area*. Two more features related to the whole signal were calculated: the number of times that
149 the amplitude value of the signal crosses the zero y-axis between two adjacent peaks (*Zero*
150 *Crossing*); and the relation of the number of crosses per time interval (*Zero Cross Density*).

151 Additionally, frequency domain features were extracted using a Power Spectral Density (PSD)
152 analysis: the frequency with the largest energy content in the signal (*Mode frequency*) spectrum; the
153 frequency that separates the power spectrum into two equal energy areas (*Median frequency*); and an
154 estimate of the central tendency of the derivate power distributions (*Mean frequency*).

155 **2.3 Classifier used in the study**

156 **2.3.1 MKL**

157 The use of MKL has shown that it enhances the interpretability of decision functions and can
158 improve classification performance compared with other classifiers (Kloft et al., 2009; Varma and
159 Babu, 2009). Similar to simple SVM applications, this method is based on kernel definitions,
160 however, instead of one single kernel, MKL combines several kernel functions (reflecting different

161 kinds of information), and also automatically determines the importance of each kernel (Gönen and
162 Alpaydin, 2011) .

163 Given a set of data X and a feature mapping function Φ , a kernel matrix can be defined as the inner
164 product of each pair of feature vectors:

$$165 \quad \mathbf{K}(\mathbf{x}_i, \mathbf{x}_j) = \langle \Phi(\mathbf{x}_i), \Phi(\mathbf{x}_j) \rangle$$

166 In the multiple kernel learning problem for binary classification, N data points $(\mathbf{x}_i, \mathbf{y}_i)$ ($\mathbf{y}_i \in \pm \mathbf{1}$) are
167 given, where \mathbf{x}_i is translated via M mappings $\Phi_m(\mathbf{x}) \rightarrow \mathbf{R}^{D_m}$, $m=1, \dots, M$, from the input into M
168 feature spaces $\Phi_1(\mathbf{x}_i), \dots, \Phi_M(\mathbf{x}_i)$ where D_m denotes the dimensionality of the m^{th} feature space.

169 Multiple Kernel Learning methods aim to construct an optimal kernel model where the kernel is a
170 linear combination of fixed base kernels. Learning the kernel then consists of learning the weighting
171 coefficients β for each base kernel, rather than optimizing the kernel parameters of a single kernel.

$$172 \quad \mathbf{K}_{opt}(\mathbf{x}_i, \mathbf{x}_j) = \sum_{m=0}^M \beta_m \mathbf{K}_m(\mathbf{x}_i, \mathbf{x}_j) \quad \beta_k > 0, \sum_{m=0}^M \beta_m = 1$$

173 When MKL is plugged into SVM, the primal form of MKL is reformulated as the following
174 optimization problem:

$$175 \quad \min_{\beta, w, b, \varepsilon} \frac{1}{2} \sum_m \frac{1}{\beta_m} \|(w_m)\|_{\mathcal{H}_m}^2 + C \sum_i \varepsilon_i$$

$$176 \quad s. t \quad \mathbf{y}_i \left(\sum_m \langle (w_m), \phi_m(\mathbf{x}_i) \rangle_{\mathcal{H}_m} + b \right) + \varepsilon_i \geq 1$$

$$177 \quad \varepsilon_i \geq 0, \text{ for } \forall i$$

$$178 \quad \sum_m \beta_m = 1, \quad \beta \geq 0$$

179 where C is a regularization parameter between training errors and an optimal separating hyperplane.
180 For binary classification MKL problem, optimization is solved using semi-infinite programming
181 (Sonnenburg et al., 2006). The three commonly used kernels are: linear kernel (\mathbf{K}_L), polynomial
182 kernel (\mathbf{K}_P), and Gaussian kernel (\mathbf{K}_G):

$$183 \quad \mathbf{K}_L(\mathbf{x}_i, \mathbf{x}_j) = \langle \mathbf{x}_i, \mathbf{x}_j \rangle$$

$$184 \quad \mathbf{K}_P(\mathbf{x}_i, \mathbf{x}_j) = (\langle \mathbf{x}_i, \mathbf{x}_j \rangle + 1)^q$$

$$185 \quad \mathbf{K}_G(\mathbf{x}_i, \mathbf{x}_j) = \exp\left(-\frac{\|\mathbf{x}_i - \mathbf{x}_j\|^2}{s^2}\right),$$

186 where parameter q is the polynomial degree and parameter s determines the width for Gaussian
187 distribution.

188 MKL provides a general framework for learning from multiple and heterogeneous data sources (de
189 Carvalho, 2019). This machine learning algorithm works by first constructing a kernel from each of
190 the data sources and then combining these kernels based on a certain criterion for improved
191 classification performance. With M kernels, a given input data can be mapped into M feature spaces.
192 Another approach is when different basis kernels are applied to the same data features to identify
193 which kernel is best for the problem at hand.

194 In this paper, the input data was mapped into different feature spaces trying to group variables with
195 common aspects: type of paradigm, channels (Fz, Cz, Pz), or type of feature. For every feature space
196 the 726 features were rearranged in three groups considering the common aspects (see **Figure 3**).
197 Then, the MKL available in SHOGUN toolbox was applied (Sonnenburg et al., 2010) for every
198 feature space. We used a non-sparse MKL with L2-norm that have more advantages over sparse
199 integration method for thoroughly combining complementary information in heterogeneous data
200 sources. L2-norm distributes the weights over all kernels while taking advantages of the effects of
201 kernels in the objective optimization (Yu et al., 2010).

202 **2.4 Feature Selection**

203 Feature selection yields a subset of features from the original set of features, which are the best
204 representatives of the data. Therefore, it allows us to reduce the number of input variables. The goal
205 of this process is to reduce the computational cost when developing a predictive model and, in some
206 cases, to improve the performance of the model, not always guarantee (Benouini et al., 2020).

207 **2.5 Boruta algorithm**

208 Boruta is a feature selection algorithm that uses a wrapper method based on the RF classifier to
209 measure the importance of variables. RF makes it relatively fast due to its simple heuristic feature
210 selection procedure (Kursa, 2017). In the Boruta algorithm, the original feature set is extended by
211 adding shadow variables (Kursa and Rudnicki, 2010). A shadow variable is created by shuffling
212 values of the original feature. The importance values are calculated for all the attributes by running
213 RF classifier resulting in a *Z score*. The maximum *Z score* is calculated among those shadow
214 variables to assign a hit for each feature that scored better than this maximum. A two-sided test of
215 equality is performed to obtain a statistically significant division between relevant and unimportant
216 feature variables. If a variable systematically falls below the shadow ones, its contribution to the
217 model is doubtful and is therefore eliminated. The shadow variables are removed and the process
218 continues until all variables are accepted, rejected or a limit number of iterations is reached. This
219 limit corresponds to the maximal number of RF runs.

220 The package “Boruta” in R was used (Kursa and Rudnicki, 2020). The implementation defaults to
221 100 as the maximum number of RF runs. To get a reduced number of attributes left undecided, this
222 value was set to 500. Nevertheless, when this value isn’t enough, another function
223 *TentativeRoughFix*, contained in the package, can be used to analyses those attributes which
224 importance is very close to the decision criteria.

225 **2.6 Nested cross validation**

226 For explore the feature selection impact, nested cross validation (NCV) was applied. The NCV is
227 characterized by having an inner loop responsible for model selection/hyperparameter tuning and an
228 outer loop is for error estimation. The entire data was divided randomly into k subsets or folds with
229 stratification, the same proportion of patients and controls as in the complete dataset. The $k-1$ subsets

230 are used for feature selection and the remaining subset for testing the model after feature selection.
231 As in k -fold cross-validation method, this process was repeated k times (outer loop), each time
232 leaving out one of the subsets reserved for testing and the rest for feature selection using Boruta
233 algorithm (see **Figure 4**).

234 Each subset obtained after feature selection, was used for model hyperparameter tuning in the inner
235 loop. One of the approaches commonly used in practice for the selection of hyperparameters is to try
236 several combinations of them and evaluate their out of sample performance. The tuned parameters in
237 the MKL classifier were:

- 238 • Regularized parameter C , a tradeoff between misclassification and simplicity of the model, the
239 candidate's values for grid was 0.5, 1, 1.5, 5, 10
- 240 • Type of kernel (linear, RBF, and polynomial)
- 241 • In case of RBF kernels the Sigma (σ) to determine the width for Gaussian distribution,
242 exploring the following values 10, 5, 1, 0.25, 0.5, 0.75.

243 The parameter configuration selected to train the final model was the one that reached the highest
244 average accuracy on the inner loop. The whole dataset used for tuning parameters was then trained
245 and tested with its corresponding test set in the outer loop. The classifiers' performance was obtained
246 by averaging the accuracy of the k trained models.

247 **3 Results**

248 **3.1 Feature Selection**

249 The Boruta algorithms yielded an average of 32 attributes selected per k iteration with values in a
250 range of 26 to 42 (see **Figure 5A**). The median computation times was around 2.6 minutes (std 0.04),
251 with 0.005 min per RF runs. A total of 76 attributes were selected at least once. **Figure 5B** shows
252 how many times these attributes were selected in the process. The distribution of variable per
253 paradigm is also showed. The 80% of the 76 attributes selected were related to amplitude, latency, or
254 the correlation between them. Attributes related to frequency domain was barely selected.

255 Only seven features were identified as important every time Boruta algorithm was used. **Table 3**
256 describes these features according to the paradigm, type of stimulus, channel, and type of feature.

257 **3.2 Classifier performance**

258 To compare the performance of the MKL algorithms three metrics derived from the confusion matrix
259 were used. As the classes were balanced, accuracy (Acc) is a good measure for assessing the
260 classification models. Accuracy is the proportion of the total number of predictions that were correct.
261 The other two measures were sensibility (Sen) that evaluates true positive rates, and specificity (Spe)
262 to evaluate the false positives rates. In **Table 4**, the performance of MKL algorithm when feature
263 selection was applied or not is shown.

264 **3.3 Discussion**

265 Here we explored the use of MKL classification algorithm for distinguishing SZs from HCs based on
266 ERP data. Using all features, the best classification accuracy (83%) was achieved when kernels were
267 built by grouping features according to paradigms. Moreover, when MKL was combined with Boruta
268 method, a classification accuracy of 86% was obtained. With this feature selection algorithm, the

269 large number of predictor variables was reduced significantly (96%) with a lower computation time.
270 Therefore, training time of MKL was also reduced, its main shortcoming is known to be its high
271 computational cost, especially when many features are used (de Carvalho, 2019).

272 Review of the Boruta algorithm results pointed out that variables with major importance were mainly
273 related with auditory P300 ERP paradigm. This correspond with the general finding that the P300
274 measures obtaining from auditory stimuli are more effective in differentiating SZs from HCs than
275 those obtaining from visual stimuli (Park et al., 2005). An interesting point to be noted is that feature
276 selected by Boruta were mainly related with amplitude, latency, and correlation between them. These
277 features correspond with Peak related features. To a lesser extend Peak to Peak related features was
278 included in the selection. However, only three features of Signal related features were rarely
279 included, thus features in frequency domain didn't contribute to classification.

280 Overall, these findings are in accordance with findings reported by other authors, and thus
281 triangulates the previous results and shows that the differences between SZs and HCs are robust even
282 when different classifiers are used. Numerous authors have been concluded that odd-ball tasks are
283 potential biomarker for diagnosis in schizophrenia. Some of them have verified that the use of
284 latency and amplitude produces similar results in the discrimination of SZs from HCs. Santos-Mayo
285 et al. used time and frequency ERP features, they explored several electrodes grouping, classifiers,
286 feature selection algorithms and filtering schemes (Santos-Mayo et al., 2017). They achieved
287 accuracies above 90% but their dataset was unbalanced and small, which could limit the
288 generalization of their findings. Shim et al. proposed to extend P300 amplitude and latency sensor-
289 level feature with cortical current density values as source-level features, due to the low spatial
290 resolution originating from volume conduction (Shim et al., 2016). Using Fisher's scores, feature set
291 ranged for 1 to 20 were selected for classification. They reported classification accuracies of 81% for
292 sensor-level features, 85% for source-level features and 88% combined them, using SVM classifier.
293 Laton et al. combined latency and amplitude features of responses to three different odd-ball tasks to
294 apply several classification algorithms (Laton et al., 2014). They achieved a classification accuracy
295 averaged 77% (3.5 std) and their best result, closed to 85%, corresponded to RF classifier. These
296 authors also found a similar pattern in terms of the most relevant features, since in a ranking of the 20
297 main variables, 14 were extracted from the P300 auditory oddball paradigm. They stated auditory
298 P300 as the most valuable of the three ERP paradigms to the final prediction success.

299 Compared with these previous studies, our accuracies values are in a range considered as a good
300 accuracy, very close to the results previously reached. This result adds robustness to the previous
301 findings remarking the possibility of accurately distinguish SZs from HCs using neurophysiological
302 measurements. The present finding confirms that Boruta algorithm is a computationally efficient and
303 robust algorithm that improves classification accuracy in many scenarios (Speiser et al., 2019).

304 Although the approach used here meet our goals, the information of the spatial voltage distributions
305 over the scalp surface was wasted. It is known that the topography across the scalp was significantly
306 different between schizophrenia and normal control groups (Morstyn et al., 1983; Frantseva et al.,
307 2014). Some authors had investigated the topographic abnormalities of schizophrenia mainly group-
308 based researches (Basile et al., 2004). However, individual patient-level analysis using topographic
309 features has been less explored for schizophrenia. This would be a fruitful area for further work in
310 other to reliably classify SZs from HCs.

311 This study suffers of small sample size as usual in psychiatric cohorts. In these cases, instead of a-
312 priori train/validate/test partitions, strategies of cross-validation allow to estimate the selected model

313 performance and avoid the risk of data leakage. Nevertheless, larger sets yield a more stable, reliable
314 estimate of future performance and guarantee better generalization (Cearns et al., 2019).

464 **5 Funding**

465 This work was supported by the VLIR-UOS project “A Cuban National School of Neurotechnology
466 for Cognitive Aging”(NSNCA), Grant number CU2017TEA436A103.

467 **6 Acknowledgments**

468 The authors would like to thank teams of Cuban Neuroscience Center and the Department of
469 Electronics and Informatics (ETRO) of Vrije Universiteit Brussel (VUB) for supporting this research
470 project.

471

472 7 ANNEX

473 Annex 1: Feature definitions

Peak related features		
Amplitude	$A_{Peak} = \max \{s(t), I_1 < t < I_2\}$, Peaks P1, P3 $A_{Peak} = \min \{s(t), I_1 < t < I_2\}$, Peaks N1, N2 $[I_1, I_2]$ Detection Interval	
Latency:	$L_{Peak} = \{t \mid s(t) = A_{Peak}\}$	
Latency/Amplitude ratio	$LAR_{Peak} = L_{Peak} / A_{Peak}$	
Absolute Amplitude	$AA_{Peak} = A_{Peak} $	
Absolute Latency/Amplitude ratio	$ALAR_{Peak} = L_{Peak} / A_{Peak} $	
Average Absolute Signal Slope	$AASS_{Peak} = \frac{1}{n} \sum_{t=I_1}^{I_2-\tau} \frac{ s(t+\tau) - s(t) }{\tau}$ τ is the signal sampling period, n the number of samples of the digital signal	
Slope sign alterations	$SSA_{Peak} = \sum_{t=I_1+\tau}^{I_2-\tau} \frac{1}{2} \left \frac{s(t-\tau) - s(t)}{ s(t-\tau) - s(t) } + \frac{s(t+\tau) - s(t)}{ s(t+\tau) - s(t) } \right $	
Peak to Peak related features		
Peak to Peak	$PP_{Peaks} = A_{Peak} - A_{NextPeak} $	
Peak to Peak Time Window	$PPT_{Peaks} = L_{NextPeak} - L_{Peak}$	
Peak to Peak Slope	$PPS_{Peaks} = PP_{Peaks} / PPT_{Peaks}$	
Signal related features		
Positive Area	$A_p = \sum_{t=-200}^{800} \frac{s(t) + s(t) }{2}$	
Negative Area	$A_n = \sum_{t=-200}^{800} \frac{s(t) - s(t) }{2}$	
Total Area	$A_{pn} = A_p + A_n$	
Absolute Total Area	$AA_{pn} = A_{pn} $	
Total Absolute Area	$AA_{pn} = A_p + A_n $	
Zero Crossing	$ZC_{Peaks} = \sum_{t=L_{Peak}}^{L_{NextPeak}} \delta_s$, $\delta_s = \begin{cases} 1 & s(t) = 0 \\ 0 & s(t) \neq 0 \end{cases}$	
Zero Cross density	$ZCD_{Peaks} = \frac{ZC_{Peaks}}{PPT_{Peaks}}$	
Mode frequency	$f_{mode} = f_j$, $P_j = \max (P_i, 1 < i < M)$	P_j is the power spectral density of signal at a frequency bin j , M is the number of frequency bin in the spectrum
Median frequency	$f_{median} \sum_{j=1} P_j = \sum_{j=f_{median}}^M P_j = \frac{1}{2} \sum_{j=1}^M P_j$	
Mean frequency	$f_{mean} = \frac{\sum_{j=1}^M f_j P_j}{\sum_{j=1}^M P_j}$	

474 **8 Tables**

475 **TABLE 1.** Demographic data.

	Patients	Controls	P (t-test)
Number of participants	54	54	
Male	36	36	
Age (years): mean \pm std	40.5 \pm 10.1	37.6 \pm 14.1	0.22
Age (years): range	[22.4, 60.5]	[15.1, 64.4]	
Education (years): mean \pm std	12.6 \pm 1.80	14.8 \pm 2.11	4.84 $\times 10^{-5}$
Disease duration (years): mean \pm std	14.8 \pm 9.04	–	
Disease duration (years): range	[1, 40]	–	

476 **TABLE 2.** Paradigms and procedures

	Auditory P300	Visual P300	
	tone	figure	distribution
Target	1500 Hz 70 dB	Square, side 106 pixels	10%
Distractor	500 Hz 70 dB	Circle, diameter 176 pixels	10%
Standard	1000 Hz 70 dB	Square, side 158 pixels	80%
Inter-stimulus interval was randomized between 1 and 1.5 seconds. 400 stimuli per test. 100 ms per stimuli. Total test time of 540 seconds.			
	MMN		
	tone	duration	distribution
duration deviant	1000 Hz 70 dB	250 ms	5%
Frequency deviant	1500 Hz 70 dB	100 ms	5%
Standard	1000 Hz 70 dB	100 ms	90%
Inter-stimulus interval of 300 ms, 1800 tones per test. Total test time of 733 seconds			

477 **TABLE 3.** Features always selected by Boruta

PARADIGM	STIMULUS	CHANNEL	PEAK	FEATURE
P300v	Target	Pz	P2	latency
P300a	Distractor	Cz	N1	absRatio
P300a	Distractor	Fz	P2	absRatio
P300a	Distractor	Fz	P2	absAmplitude
P300a	Target	Cz	N1	absRatio
P300a	Target	Cz	N2	latency
P300a	Target	Cz	P2	latency

478 **Table 4.** Performance (%) of MKL algorithm with and without Boruta feature selection

MKL Kernels	Without FS			With FS		
	Acc	Sen	Spe	Acc	Sen	Spe
Paradigm	83	80	88	86	86	87
Channels	80	74	87	84	85	86
Type of Features	82	78	85	86	86	86

479 **9 Figures**

480 **FIGURE 1.** Averaged evoked potential signals used for feature extraction.

481 **FIGURE 2.** Principal components of P300 tasks (N100, P200, N200, P300) and MMN task (P200,
482 P300).

483 **FIGURE 3.** Grouping input data (726 features) in three possible kernel combinations according to
484 the feature space approach.

485 **FIGURE 4.** Feature selection steps applying nested cross validation.

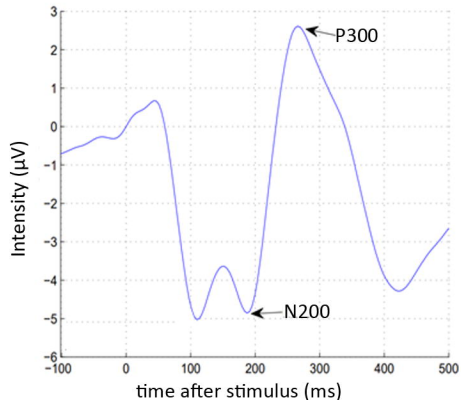

486 **FIGURE 5.** Distribution of feature selection in 10-fold-cross-validation. **(A)** Distribution per
487 paradigm in the 10 subsets of features selected. **(B)** Frequency of selection of all the attributes that
488 were selected in the ten Boruta applications. The bottom number means how many features were
489 selected the number of times represented in the top number.
