ABSTRACT

Background
Seroprevalence studies provide an accurate measure of SARS-CoV-2 spread at a population level and the number of undiagnosed individuals. Repeated cross-sectional sero-studies are encouraged to monitor the spread of the virus. The aim of this study is to assess the seroprevalence rate among a random sample of Palestinians residing in the West Bank region of Palestine.

Methods
This second round cross-sectional study involved 1451 participants, who agreed to be interviewed and answer the questionnaire, where 910 of them agreed to participate in the sero-study and donate a blood sample to be tested for antibodies. The sample was randomly selected from the adult population, 18 years or older, living the West Bank region of Palestine.

Serological tests for 910 adequate serum samples were done using immunoassays for detection of antibodies against SARS-CoV-2. Sociodemographic information and medical history data was collected.

Results
Study findings indicate that as of October 2021, a seroprevalence rate of 75.9% (30% due to infection with Covid-19 virus and 45.9% due to vaccination) , 95% CI (73.1-78.7). The results indicate that the prevalence of antibodies among those who are unvaccinated and undiagnosed was 45.2% with 95% CI (39.9-50.5%).

The average age of participants was 37.6 years old. 49.2% were females and 50.8% were males. In relation to COVID-19, 13.6% of respondents reported getting infected by Covid-19 with statistically significant difference (P_value=0.001) between males (10.7%) and females (16.5%). . In terms of vaccination, 52.8% of respondents reported getting vaccinated with an important difference between males (64.3%) and females (40.9%), (P-value=0.000).

Conclusion
 Our findings reveal a drastic rise in seroprevalence of SARS-CoV-2 antibodies due to infection and vaccination. This information is useful for assessing the degree of herd immunity among the adult population and provides better understanding of the pandemic. Population-based seroprevalence studies should be conducted periodically to monitor the SARS-CoV-2 seroprevalence in Palestine and inform policymakers about the efficacy of the surveillance system and the public compliance with vaccination policies especially among females

INTRODUCTION

Severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2), a novel virus that causes Coronavirus Disease 2019 (COVID-19) has infected over 460 million and caused the deaths of over six million people worldwide as of March 12, 2022 [1]. However, these figures underestimate the accurate cumulative prevalence or incidence of infection [2], due to lack of accessibility of diagnostic testing, limited testing capacity [3] , and asymptomatic infections [4].

Globally, seroprevalence studies using serologic testing have been recognized to provide better estimates of COVID-19 infection rates and prevalence on a population level in different populations, by capturing individuals with mild or no symptoms and others who never underwent diagnostic testing [5]. Assessing the cumulative prevalence is critical to understanding disease transmission rates and for understanding the evolution of the pandemic [5, 6]. The true prevalence of infection is believed to be 12.5 times more than the number of PCR-reported infections [7] as there are many asymptomatic infections, which constitute the majority of all SARS-COV-2 infections, yet are less likely to present for diagnostic testing [8, 9]. Consequently, the accuracy of such seroprevalence studies has been doubted due to insufficient specificity of the serologic assay for a low prevalence population and due to potential sampling bias [10].

In March 2020 a nationwide lockdown was implemented in Palestine, to contain the spread of COVID-19. As of March 2022, approximately 580,165 infections have been recorded, and 5,326 people have died in Palestine [11]. Previously, the authors of this study undertook a cross-sectional study [12] which revealed 0% seroprevalence of SARS-CoV-2 among a random sample of adults in the general population in the West Bank region of Palestine. Other studies [13] conducted among the visitors of primary health care centers in Paelstine showed 36% seroprevalence. A large scael sero survey was conducted by the Paesitnian ministry of health and WHO produced a seroprevalence of 40% among the general population who are 10 years or older in the West Bank and Gaza [18]. There is a lack of data on the percentage of undiagnosed Palestinian population with previous mild or asymptomatic COVID-19. This rsecond round cross-sectional study was conducted to assess the seroprevalence of SARS-CoV-2 among a national sample of vaccinated and non-vaccinated adults in the West Bank region of Palestine, be it due to infection with COVID-19 or due to vaccination or both. A substantial seroprevalence of anti-SARS-CoV-2 antibodies in the Palestinian population should provide some measure of protection against future waves of COVID-19 in the country.

METHODS
Study design and participants
This second round cross-sectional study was conducted between September 14, 2021 and October 21, 2021. The study included a random sample of adults aged 18 years and above, residing in 11 governorates in the West Bank, Palestine. The sample included 1451 individuals

randomly selected from households using three-stage cluster sampling. The cluster of households or census tracts is considered to be a geographic location which is comprised of 124 households. The process for conducting cluster sampling included: (1) Selection of 125 census tracts (clusters) of households using the sampling frame provided by the Palestinian Central Bureau of Statistics (PCBS), (2) Selection of 16 households randomly from each cluster and (3) selection of individuals at random from the list of individuals who are over the age of 18 and belong to the selected household. The clusters were selected using probability proportional to size (PPS) sampling, see Table (1). The following steps were used to select the number of clusters within each population location: (1) the sampling interval (eg $SI=N/m$) which equals the total number of households divided by the total number of clusters need to be selected by the sample was calculated, (2) a random number R_0 between 0 and SI was calculated, and (3) calculated R_i as R_0+i*SI, a cluster is selected in L_i if R_i belongs to the interval $[C_{i-1}, C_i]$.

Table 1: The PPS sampling algorithm for selecting population locations.

Location	# of households in the location	Cumulative
L1	X1	C1=X1
L2	X2	C2=X1+X2
L3	X3	C3=X1+X2+X3
.	.	.
.	.	.

Lk-1	Xk-1	Ck-1=X1+X2+…+Xk-1
Lk	Xk	Ck = X1+X2+…+Xk
PPS, probability proportional to size.		

Data Collection
Sociodemographic information, risk factors, medical history, and COVID-19 related information (eg. Symptoms (due to infection or due to vaccination); vaccination status) were obtained during a face-to-face interview from 1451 participants (Table 2). Upon the interview, 911 participants gave consents to test for antibodies against COVID-19. Blood samples were collected from the participants. Blood samples were centrifuged, and serum was separated, labelled and stored at −20°C at AAUP laboratory until it was used.

Data collection was conducted by healthcare professionals following standardized health protocols (World Health, 2020). Ethics approval was obtained from the Helsinki committee ((PHRC/HC/737/20).) Participants recruited in the study gave written consent forms prior to participation in the study voluntary agreeing to participate in the research.

The study was conducted between September 14th 2021 and October 21st . Demographic and health Data was collected through face to face interviews with the 1451 participants. Blood samples were drawn from 911 participants who agreed to participate in the sero study.

Table (2): Sample Characteristics

Background variable		N	%
Gender	Male	737	50.8%
	Female	714	49.2%
Marital Status	Never married	377	26.0%
	Engaged	33	2.3%
	Married	935	64.4%
	Divorced	21	1.4%
	Widowed	81	5.6%
	Separated	5	0.3%
Highest Degree Obtained	illiterate	57	3.9%
	Knows how to read and write	68	4.7%
	Elementary	216	14.9%
	Preparatory	396	27.3%
	Secondary	336	23.2%
	Two or one year diploma	81	5.6%
	Bachelor	273	18.8%
	Higher diploma	2	0.2%
	Masters	18	1.3%
	Ph.D.	3	0.2%
Refugee Status	Registered refugee	357	24.6%
	Unregistered refugee	15	1.0%
	Not a refugee	1078	74.3%
Age category in years	18-29	561	38.6%
	30 -49	568	39.2%
	50 +	322	22.2%

Sars-CoV-2 Antibody Testing

Serological tests for the 911 adequate serum samples were done using an Elecsys® Anti-SARS-CoV-2 assay by using the Cobas Analyzer cobas e 411 (Roche). The assay is an immunoassay that uses a recombinant protein representing the nucleocapsid (N) antigen. Serum samples in which the nucleocapsid (N) antigen was not detected were run using Elecsys Anti-SARS-CoV-2 S by using the Cobas Analyzer cobas e 411 (Roche). The assay detects antibodies to SARS☐CoV☐2 spike protein RBD which are produced by mRNA vaccines. Samples from recovered and vaccinated cases with detected SARS-CoV-2 anti N and SARS-CoV-2 anti S antibodies were run as positive controls.

Statistical Analysis

Both univariate and bivariate inferential statistical methods were used for statistical analysis. Confidence interval using 95% confidence levels are used for estimation the seroprevalence across different segments within the Palestinian adult population living in the West Bank region. The lower and upper confidence limits of were calculated. Cross-tabulation method was used to explore bivariate relationships between seroprevalence and gender among other background variables. Chi-square test was utilized for testing if the statistical significance of bivariate relations among the different variables.

RESULTS

Sample Characteristics

In total, 1451 participants were enrolled in the study in which 911 undertook serological testing and blood sampling. Among these, 50.8% were males, 64.4% were married, 27.3% finished preparatory school, and 74.4% were non-refugees. The mean age of participants is 37.6. See Table (2) for detailed sample characteristics.

The main findings of the survey showed that a large majority of adult Palestinians (75.9%) developed antibodies against COVID-19. The results did not show significant difference (P-value=0.23) between males (74.2%) and females (77.5%) in the overall seroprevalence, see Table (3). While there was a strong difference according to gender when we accounted for the source of antibodies whether it was due to infection or vaccination. The results showed that the prevalence of antibodies due to infection among females was twice (41.2%) that among males (19.9%) ,(P-value=0.000). See Table (6).

The study results showed quite a significant difference (P-value=0.000) in antibodies prevalence across age groups in the Palestinians society. The youngest age group (18-29 years) recorded the lowest prevalence of antibodies (69.2%), while the age group (30 -50 years) showed a prevalence of 77.9%. While the older group (50 years or older) got the highest prevalence of antibodies (84.1%). Such result could be attributed to the fact that the older population categories got more vaccinated than the younger population categories, see Table (4).

Table (3): Antibodies test results irrespective of he source (infection or vaccine) by gender

			Gender		Total
			Male	Female	
Antibodies test result	Negative	Count	114	105	219
		% within Gender	25.8%	22.4%	24.1%
	Positive	Count	328	363	691
		% within Gender	74.2%	77.6%	75.9%

a. 0 cells (0.0%) have expected count less than 5. The minimum expected count is 106.37.

b. Computed only for a 2x2 table

An important factor that explained the variation in levels of antibodies prevalence is the vaccination and infection status among the Palestinian population. A new variable was computed based on the infection status with Covid-19 and the vaccination status. The new variable was used to segment the Palestinian population over the age of 18 into four categories described as follows: a) individuals who got infected and got vaccinated, b) individuals who got infected and did not get vaccinated, c) individuals who did not get infected and got vaccinated, d) individuals who did not get infected and did not get vaccinated.

Table (4): Antibodies test results irrespective of the source (infection or vaccine) by age category

			Age category in years			
			18-29	30 -49	50 +	Total
Antibodies test result	Negative	Count	113	71	35	219
		% within Age category in years	30.8%	22.0%	15.8%	24.1%
	Positive	Count	254	251	186	691
		% within Age category in years	69.2%	78.0%	84.2%	75.9%

Chi-Square Tests (I don't think its an appropriate title)

	Value	df	Asymptotic Significance (2-sided)
Pearson Chi-Square	17.986[a]	2	.000
Likelihood Ratio	18.297	2	.000
Linear-by-Linear Association	17.789	1	.000
N of Valid Cases	910		

a. 0 cells (0.0%) have expected count less than 5. The minimum expected count is 53.19.

The largest group of individuals within the Palestinian adult population living in the West Bank region are those who did not get infected and got vaccinated (46.4%) followed by the second largest group, which represents those who did not get vaccinated and reported (thought) that they did not get infected (40.0%) , see Figure (1).

Our findings showed a strong bivariate relationship between antibody test results and infection-vaccination status (P-value=0.000) , see Table (5). It is evident, the antibodies prevalence among those who did not get infected and got vaccinated is 94.0% in comparison to 45.2% among those who reported that they did not get vaccinated and did not get infected as well. Interestingly, 45.2% of those who did not get vaccinated and reported that they did not get infected with Covid-19 actually got infected without knowing, concluding this group of the population were asymptomatic to the infection.

Figure (1): Distribution of vaccination and Covid-19 infection status for adult Palestinians living in the West Bank region of Palestine.

DISCUSSION

The present study reports the seroprevalence of anti-SARS-CoV-2 antibodies as of October 2021. There have not been many studies assessing seroprevalence after the beginning of vaccinations. According to this study, seroprevalence of antibodies due to infection with COVID-19 or vaccination one and half years after the start of the pandemic and several months after the vaccination rollout was 75.9%, varying among age groups, with the youngest age group having the highest seroprevalence . The high seroprevalence rate of antibodies   observed in our cohort was surely influenced by the high rate of vaccination within the Palestinian adults living in the West Bank region. This finding was similar to a study conducted in Chile in which reported a similar seroprevalence of 77.4% five months after initiation of the vaccination [14]. Similar to the Chile study, the results of our study showed a significant difference across gender in antibodies prevalence when we account for the source of positivity with antibodies whether it's due to infection with Covid-19 or due to vaccination, see Table (6). This result is consistent

with other studies which found a statistically significant difference between prevalence of antibodies and

Table (5): Antibodies test results by vaccination and Covid-19 infection status as reported by respondents

Chi-Square Tests

	Value	Df	Asymptotic Significance (2-sided)
Pearson Chi-Square	285.275[a]	3	.000
Likelihood Ratio	294.040	3	.000
Linear-by-Linear Association	62.356	1	.000
N of Valid Cases	910		

a. 0 cells (0.0%) have expected count less than 5. The minimum expected count is 14.44.

gender, [14],[15]. At the regional level, a three phased seroprevalence survey was conducted in Jordan, where results revealed that seroprevalence dramatically increased over time, with only a tiny fraction of seropositive individuals in August 2020 (0.3%), to increase up to more than 20-fold in October 2020 (7.0%) and to reach one-third of the overall population exposed by the end of 2020 (34.2%), [15]. Such results are compatible with similar seroprevalence survey conducted by the Palestinian ministry of health and WHO at the end of 2020 [18]. While similar results were obtained by a seroprevalence survey conducted by Arab American university in during June 2020. [12]. The most recent serology survey conducted by CDC over the period of September 2021 till December 2021 in the US, Seroprevalence increased from 36.5% (95% CI = 35.7–37.4) to 63.7% (95% CI = 62.5–64.8) among adults aged 18–49 years, 28.8% (95% CI = 27.9–29.8) to 49.8% (95% CI = 48.5–51.3) among those aged 50–64 years, and from 19.1% (95% CI = 18.4–19.8) to 33.2% (95% CI = 32.2–34.3) among those aged ≥65 years, [16]. Approximately similar seroprevalence due to infection with Covid-19 (30%) was obtained by our serology survey that targeted adults over the age of 18 year during September 2021. See Table (6).

Two years after the start of the COVID-19 pandemic, the actual prevalence of infection is still underestimated compared with PCR-confirmed COVID-19 cases. Older compared with younger individuals have lower antibody levels after vaccination. Approximately, 40% of the Palestinian adult population over the age of 18 years thought they were not infected and did not make the effort to get vaccinated. The study's findings showed 45% of those who thought they were not infected and did not get vaccinated, tested positive for SARS Covid-2 antibodies. By multiplying these two percentages, one can conclude that 18% of the Palestinian adult population who are over the age 18 got infected with SARS Covid-2 without knowing. This group of people could have contributed to a faster transmission rate in the spread of the virus, since they were asymptomatic. Governments and public health officials should put more effort to detect asymptomatic cases through conducting seroprevalence surveys on a regular basis and develop regulations to encourage more people to get vaccinated. Tracking seroprevalence due to vaccination is an important issue, since vaccination contributes to the reduction of hospitalization among Covid-19 patients. A preliminary evidence has highlighted a possible association between severe COVID-19 and persistent cognitive deficits[17]. Further research is required to confirm this association, determine whether cognitive deficits relate to clinical features from the acute phase or to mental health status at the point of assessment, and quantify rate of recovery.

Table (6): Seroprevalence according to gender and source of antibodies (infection or vaccine)
