Running Head: The SOFA score for predicting mortality in ICU patients with sepsis in Vietnam

Article Type: Research / Original Paper

Word Count:

- Abstract: 300 words

- Formal scientific presentations: 3769 words and 51 references, plus a structured abstract

Figure/Table: 7

ABSTRACT

Objectives: To compare the accuracy of the SOFA and APACHE II scores in predicting mortality among ICU patients with sepsis in an LMIC.

Design: A multicentre, cross-sectional study.

Setting: A total of 15 adult ICUs throughout Vietnam.

Participants: We included all patients aged ≥ 18 years who were admitted to ICUs for sepsis and who were still in ICUs from 00:00 hour to 23:59 hour of the specified study days (i.e., 9th January, 3rd April, 3rd July, and 9th October of the year 2019).

Primary and secondary outcome measures: The primary outcome was hospital all-cause mortality (hospital mortality). We also defined the secondary outcome as all-cause deaths in the ICU (ICU mortality).

Results: Of 252 patients, 40.1% died in hospitals, and 33.3% died in ICUs. SOFA (AUROC: 0.688 [95% CI: 0.618-0.758]; cut-off value ≥ 7.5 ; $P_{\text{AUROC}} < 0.001$) and APACHE II scores (AUROC: 0.689 [95% CI: 0.622-0.756]; cut-off value ≥ 20.5 ; $P_{\text{AUROC}} < 0.001$) both had a poor discriminatory ability for predicting hospital mortality. However, the discriminatory ability for predicting ICU mortality of SOFA (AUROC: 0.713 [95% CI: 0.643-0.783]; cut-off value ≥ 9.5 ; $P_{\text{AUROC}} < 0.001$) was fair and was better than that of APACHE II score (AUROC: 0.672 [95% CI: 0.603-0.742]; cut-off value ≥ 18.5 ; $P_{\text{AUROC}} < 0.001$). A SOFA score ≥ 8 (adjusted OR: 2.717; 95% CI: 1.371-5.382) and an APACHE II score ≥ 21 (adjusted OR: 2.668; 95% CI: 1.338-5.321) were independently associated with an increased risk of hospital mortality. Additionally, a SOFA score ≥ 10 (adjusted OR: 2.194; 95% CI: 1.017-4.735) was an

independent predictor of ICU mortality, in contrast to an APACHE II score ≥ 19 , for which this role did not.

Conclusions: In this study, SOFA and APACHE II scores were worthwhile in predicting mortality among ICU patients with sepsis. However, due to better discrimination for predicting ICU mortality, the SOFA was preferable to the APACHE II score in predicting mortality.

Keywords: APACHE II Score; Emergency Department; Intensive Care Unit; Sepsis; Septic Shock; SIRS; SOFA Score.

Clinical trials registry – India: CTRI/2019/01/016898

Strengths and limitations of this study

- An advantage of the present study was data from multi centres, which had little missing data.
- Due to the absence of a national registry of intensive care units (ICUs) to allow systematic recruitment of units, we used a snowball method to identify suitable units, which might have led to the selection of centres with a greater interest in sepsis management.
- Due to the study's real-world nature, we did not make a protocol for microbiological investigations. Moreover, we mainly evaluated resources utilized in ICUs; therefore, the data detailing the point-of-care testing and life-sustaining treatments were not available. Additionally, to improve the feasibility of conducting the study in busy ICUs, we opted not to collect data on antibiotic resistance and appropriateness.

- Due to our independent variables (e.g., SOFA score that was greater than or equal to the cut-off value) that might be associated with primary outcome only measured upon ICU admission, the mixed-effects logistic regression model could not be used to predict discrete outcome variables measured at two different times, i.e., inside and outside the ICU settings.
- Although the sample size was large enough, the confidence interval was slightly wide ($\pm 6.03\%$), which might influence the normal distribution of the sample.

INTRODUCTION

Sepsis is a clinical syndrome which has physiologic, biologic, and biochemical abnormalities caused by a dysregulated host response to infection and is a critical global health problem.(1, 2) Sepsis is the most common cause of in-hospital deaths, with most of the burden in low- and middle-income countries (LMICs), and extracts a high economic and social cost;(3-5) mortality rates remain high at 30-45% and contribute to as much as 20% of all deaths worldwide.(2, 4, 6, 7) There is no reference standard that allows easy, accurate diagnosis and prognosis of sepsis.(1, 8) Although the 1991 International Consensus Definition Task Force proposed the systemic inflammatory response syndrome (SIRS) criteria to identify patients with a septic host response,(9) these criteria do not measure whether the response is injurious, and their utility is limited.(1, 8).

The Acute Physiology and Chronic Health Examination II (APACHE II) score was originally developed for critically ill patients in intensive care units (ICUs).(10) It has 12 physiologic measures and extra points based upon age and the presence of chronic disease.(10) The APACHE II score was shown to have good prognostic value in acutely ill or surgical patients.

(10, 11) However, some limitations of the APACHE II score are that (i) it is complex and cumbersome to use, (ii) it does not differentiate between the sterile and infected necrosis, and finally, (iii) it has a poor predictive value at 24 hours.(12)

In 2016, the Sepsis-3 Task Force proposed that for patients with suspected infection, an increase of 2 points or more in the Sequential (Sepsis-Related) Organ Failure Assessment (SOFA) score could serve as clinical criteria for sepsis,(1) and the consensus has not changed since then.(13) This approach was justified based on content validity (SOFA reflects the facets of organ dysfunction) and predictive validity (the proposed criteria predict downstream events associated with the condition of interest).(14-17) However, the validity of this score was mainly derived from critically-ill patients with suspected sepsis by interrogating over a million intensive care unit (ICU) electronic health record encounters from ICUs in high-income countries (HICs).(1, 17, 18) Moreover, the patients, pathogens, and clinical capacity to manage sepsis differ considerably between HIC and LMIC settings.(7) Therefore, it's still unclear whether this score could be applied to different types of infection, locations within the hospital, and countries.

Vietnam is an LMIC, ranked 15th in the world and 3rd in Southeast Asia by population with 96.462 million people.(19) Vietnam is also a hotspot for emerging infectious diseases in Southeast Asia, including the SARS-CoV,(20) avian influenza A(H5N1),(21, 22) and ongoing global COVID-19 outbreaks(23, 24). Additionally, severe dengue,(25) *Streptococcus suis* infection,(26) malaria,(27) and increased antibiotic resistance are other major causes of sepsis in ICUs across Vietnam(28, 29). Despite its recent economic growth spurt,(30) Vietnam is still struggling to provide either enough resources or adequate diagnostic, prognostic and treatment strategies for patients with sepsis in both local and central settings.(31, 32) In addition, within the healthcare system in Vietnam, central hospitals are

responsible for receiving patients who have difficulties being treated in local hospital settings.(33) Therefore, the diagnosis, prognosis, and initiation of treatment for patients with sepsis are often delayed.

In resource-limited settings, the early identification of infected patients who may go on to develop sepsis or may be at risk of death from sepsis using accurate scoring systems as a way to decrease sepsis-associated mortality. Therefore, this study aimed to investigate the mortality rate and compare the accuracy of the SOFA score and the APACHE II score in predicting mortality in ICU patients with sepsis in Vietnam.

METHODS

Source of data

This multicentre observational, cross-sectional, point prevalence study is part of the Management of Severe sepsis in Asia's Intensive Care unitS (MOSAICS) II study,(34-37) which enrolled patients on 9th January (Winter), 3rd April (Spring), 3rd July (Summer), and 9th October (Autumn) of the year 2019. All patients received a follow-up till hospital discharge, death in the ICU/hospital, or up to 90 days post-enrolment, whichever was earliest. In this study, we used only data from Vietnam. A total of 15 adult ICUs (excluding predominantly neurosurgical, coronary, and cardiothoracic ICUs) participating in the MOSAICS II study from 14 hospitals, of which 5 are central and 9 are provincial, district, or private hospitals, throughout Vietnam. Each ICU had one or two representatives who were part of the local study team and the MOSAICS II study group, as shown in eAppendix 2 of a previously published paper(36). Participation was voluntary and unfunded.

Participants

All patients admitted to participating ICUs on one of the four days (i.e., January 9th, April 3rd, July 3rd, and October 9th, 2019) which represented the different seasons of the year 2019 were screened for eligibility. We included all patients, aged ≥ 18 years old, who were admitted to the ICUs for sepsis, and who were still in the ICUs from 00:00 hour to 23:59 hour of the study days. We defined sepsis as infection with a SOFA score of 2 points or more from baseline (assumed to be 0 for patients without prior organ dysfunction).(1)

Data collection

We used a standardized classification and case record form (CRF) to collect data on common variables as shown in Supplementary file 1. The data dictionary of the MOSAICS II study is available as an online supplement of previously published papers.(35, 36) Data was entered by the representatives of the participating hospitals into the database of the MOSAICS II study via the password-protected online CRFs. We checked the data for implausible outliers and missing fields and contacted ICU representatives for clarification. We then merged the data sets for the 14 hospitals.

Outcome measures

The primary outcome was hospital all-cause mortality (hospital mortality). We also defined the secondary outcomes as all-cause deaths in the ICU (ICU mortality) and the ICU and hospital lengths of stay (LOS).

Predictor measures

We defined exposure variables as the SOFA and the APACHE II scores.(10, 14) All data elements required for calculating the SOFA score at the time of ICU admission and the

APACHE II score over the first 24 hours of ICU admission were prospectively collected on a CRF and entered into a database via the online CRF for later analysis.

We determined confounding factors as the variables of hospital and ICU characteristics collected on a questionnaire by representatives before patient enrolment, as shown in Supplementary file 2. We also determined confounding factors as variables collected on a CRF by investigators. The CRF contained 4 sections which is available in Supplementary file 1. The first section focused on baseline characteristics (demographics, documented comorbidities, and details of admission). The second section comprised of vital signs upon ICU admission, laboratory parameters, site of infection, and microbiology. Only microorganisms detected via all cultures, serology, molecular, and histological investigations and deemed to be true pathogens rather than commensals or contaminants were recorded. The third section captured the timing of sepsis bundle elements referencing time zero, determined as follows: (a) time of triage in the emergency department (ED) for those presenting with sepsis to the ED; (b) time of clinical documentation of deterioration in the general wards or other non-ED areas for those who developed sepsis after hospital admission; (c) time of ICU admission for those in which (a) or (b) could not be determined from the clinical documentation. The bundle elements were based on the Surviving Sepsis Campaign's 2018 update: antibiotics administration, blood cultures, lactate measurement, fluid administration (amount of fluids administered in the first and third hours from time zero) and vasopressor initiation.(38) The fourth section concerned life-sustaining treatments provided during the ICU stay.

Sample size

In the present study, hospital mortality served as the primary outcome. We, therefore, used the formula to determine the minimal sample size for estimating a population proportion with

a confidence level of 95%, a confidence interval (margin of error) of 6.03% and an assumed population proportion of 61.0%, based on the hospital mortality rate (61.0%) of our cohort reported in a previously published study(39). Therefore, we should have at least 252 patients in our sample. Because of this, our sample size was sufficient and reflected a normal distribution.

$$n = \frac{z^2 x \hat{p}(1 - \hat{p})}{\varepsilon^2}$$

where:

z is the z score (z score for a 95% confidence level is 1.96)

ε is the margin of error (*ε* for a confidence interval of ± 6.03% is 0.0603)

ĥ is the population proportion (*ĥ* for a population proportion of 61.0% is 0.61)

n is the sample size

Statistical analyses

We used IBM® SPSS® Statistics 22.0 (IBM Corp., Armonk, United States of America) for data analysis. We report data as numbers (no.) and percentages (%) for categorical variables and medians and interquartile ranges (IQRs) or means and standard deviations (SDs) for continuous variables. Comparisons were made between survival and death in the hospital and ICU for each variable, using the Chi-squared test or Fisher exact test for categorical variables and the Mann-Whitney U test, Kruskal-Wallis test, one-way analysis of variance for continuous variables.

Receiver operator characteristic (ROC) curves were plotted and the areas under the receiver operating characteristic curve (AUROC) were calculated to determine the discriminatory ability of the SOFA and APACHE II scores for deaths in the hospital and ICU. The cut-off value of the SOFA and the APACHE II scores was determined by the ROC curve analysis

and defined as the cut-off point with the maximum value of Youden's index (i.e., sensitivity + specificity – 1). Based on the cut-off value of the scores, we assigned the patients to two groups: either a score that was less than the cut-off value or a score that was greater than or equal to the cut-off value.

We assessed factors associated with death in the hospital using logistic regression analysis. To reduce the number of predictors and the multicollinearity issue and resolve the overfitting, we used different ways to select variables as follows: (a) we put all variables (including exposure and confounding factors) of hospital and ICU characteristics, baseline characteristics, clinical and laboratory characteristics, and treatments into the univariable logistic regression model; (b) we selected variables if the P-value was <0.05 in the univariable logistic regression analysis between survival and death in the hospital, as well as those that are clinically crucial to put in the multivariable logistic regression model. These variables included university affiliation, training program in ICU, documented comorbidities (i.e., cardiovascular disease, chronic neurological disease), the severity of illness (i.e., SOFA and APACHE II scores that were greater than or equal to the cut-off value), sites of infection (i.e., urinary tract, abdominal, skin or cutaneous sites), pathogens detection (i.e., no pathogens detected, Gram-negative bacteria), completion of the 1- or 3-hour sepsis bundle of care, completion of the initial administration of antibiotics within 1 or 3 hours, respiratory support (i.e., mechanical ventilation (MV), high-flow nasal oxygen), and additional ICU support (i.e., vasopressors/inotropes, renal replacement therapy (RRT), red blood cell transfusion, platelet transfusion, fresh frozen plasma transfusion, surgical source control, and non-surgical source control). Using a stepwise backward elimination method, we started with the full multivariable logistic regression model that included the selected variables. This method then deleted the variables stepwise from the full model until all remaining variables

were independently associated with the risk of death in the hospital in the final model. Similarly, we used these methods of variable selection and analysis for assessing factors associated with death in the ICU. We presented the odds ratios (ORs) and 95% confidence intervals (CIs) in the univariable logistic regression model and the adjusted odds ratios (AORs) and 95% CIs in the multivariable logistic regression model.

For all analyses, significance levels were two-tailed, and we considered $p < 0.05$ as statistically significant.

Patient and public involvement

Patients or the public were not involved in the design, or conduct, or reporting, or dissemination plans of our research.

RESULTS

Data on 252 patients with sepsis were submitted to the database of the MOSAICS II study (Fig. 1), in which there were little missing data.

Figure 1. Flowchart of the study design, patient enrolment and follow-up (Abbreviations: ICU, intensive care unit; “**discharged to die**”, defined as the patients were in grave condition or dying and were classified with deaths in the ICU at the time of discharge).

Clinical characteristics and outcomes

In our study cohort, 64.3% (162/252) were men and the median age was 65 years (IQR: 52–76.75) (Table 1). Among the total patients, the median SOFA score was 7 (IQR: 4.75–10) at the time of ICU admission, the median APACHE II score was 18 (IQR: 13–24) over the first

24 hours of ICU admission, and 29.4% (74/252) of patients had septic shock (Table 1). Table 1 also shows that the most common documented comorbidities included cardiovascular disease (31.0%; 78/252), diabetes mellitus (26.6%; 67/252), and chronic neurological disease (14.3%; 36/252), the most common sites of infection included respiratory (56.7%; 143/252), abdominal cavity (24.2%; 61/252), urinary tract (14.7%; 37/252) and skin or cutaneous sites (7.5%; 19/252) and Gram-negative bacteria were isolated in 61.9% (156/252) of patients. Table 2 shows that MV was provided for 68.9% (173/251) of patients and RRT for 40.2% (101/251). Overall, 40.1% (101/252) of patients with sepsis died in the hospital, 33.3% (84/252) of whom died in the ICU (Fig. 1 and Table 2). The median hospital and ICU LOS were 16 (IQR: 10–25) and 10 (IQR: 6–18) days, respectively (Table 2). The clinical characteristics, severity of illness, sites of infection and microbiology, compliance with sepsis bundle elements, and life-sustaining treatments during ICU stay were compared between patients who survived and patients who died in the hospital and ICU, as shown in Tables 1 and 2, and Tables S1–S14 (Supplementary file 3).

Table 1. Baseline characteristics according to hospital survivability of patients with sepsis

Overall prognostic performance of the severity scoring systems

The SOFA score (AUROC: 0.688 [95% CI: 0.618–0.758]; cut-off value ≥ 7.5 ; sensitivity: 64.4%; specificity: 69.8%; $P_{\text{AUROC}} < 0.001$) and APACHE II score (AUROC: 0.689 [95% CI: 0.622–0.756]; cut-off value ≥ 20.5 ; sensitivity: 61.4%; specificity: 71.8%; $P_{\text{AUROC}} < 0.001$) both had a poor discriminatory ability for the hospital mortality (Fig. 2). The discriminatory ability for the ICU mortality of SOFA score (AUROC: 0.713 [95% CI: 0.643–0.783]; cut-off value ≥ 9.5 ; sensitivity: 53.6%; specificity: 80.1%; $P_{\text{AUROC}} < 0.001$), however, was fair and was better than that of the APACHE II score (AUROC: 0.672 [95% CI: 0.603–0.742]; cut-off value ≥ 18.5 ; sensitivity: 69.0%; specificity: 60.8%; $P_{\text{AUROC}} < 0.001$) (Fig. 3).

Figure 2. Comparisons of the AUROCs: Comparing the overall diagnostic performance of the SOFA score (AUROC: 0.688 [95% CI: 0.618–0.758]; cut-off value ≥ 7.5 ; sensitivity: 64.4%; specificity: 69.8%; $P_{\text{AUROC}} < 0.001$) and the APACHE II score (AUROC: 0.689 [95% CI: 0.622–0.756]; cut-off value ≥ 20.5 ; sensitivity: 61.4%; specificity: 71.8%; $P_{\text{AUROC}} < 0.001$) for predicting hospital mortality in ICU patients with sepsis (Abbreviations: **APACHE II**: Acute Physiology and Chronic Health Evaluation II score; **AUROC**: areas under the receiver operating characteristic curve; **CI**: confidence interval; **ICU**: intensive care unit; **ROC**: receiver operator characteristic curve; **SOFA**: Sequential Organ Failure Assessment score).

Figure 3. Comparisons of the AUROCs: Comparing the overall diagnostic performance of the SOFA score (AUROC: 0.713 [95% CI: 0.643–0.783]; cut-off value ≥ 9.5 ; sensitivity: 53.6%; specificity: 80.1%; $P_{\text{AUROC}} < 0.001$) and the APACHE II score (AUROC: 0.672 [95% CI: 0.603–0.742]; cut-off value ≥ 18.5 ; sensitivity: 69.0%; specificity: 60.8%; $P_{\text{AUROC}} < 0.001$) for predicting ICU mortality in ICU patients with sepsis (Abbreviations: **APACHE II**: Acute Physiology and Chronic Health Evaluation II score; **AUROC**: areas under the receiver

operating characteristic curve; **CI**: confidence interval; **ICU**: intensive care unit; **ROC**: receiver operator characteristic curve; **SOFA**: Sequential Organ Failure Assessment score).

Risk factors for mortality

In the multivariable analysis, a SOFA score of 8 and above (AOR: 2.717; 95% CI: 1.371–5.382) and an APACHE II score of 21 and above (AOR: 2.668; 95% CI: 1.338–5.321) that were independently associated with an increased risk of hospital mortality (Table 3). Additionally, a SOFA score of 10 and above (AOR: 2.801; 95% CI: 1.332–5.891) was independently associated with an increased risk of ICU mortality, in contrast to an APACHE II score of 19 and above, for which this independent association was not observed (Table 4). Other factors were significantly or independently associated with the risk of hospital and ICU mortalities, as shown in Tables 3 and 4, and Tables S15–S18 (Supplementary file 3).

DISCUSSION

Of 252 patients with sepsis included in our analysis, two-fifths (40.1%) died in the hospital, and about a third (33.3%) died during the ICU stay (Fig. 1 and Table 2). The SOFA and APACHE II scores had a poor discriminatory ability for predicting hospital mortality (Fig. 2). However, the overall performance of the SOFA score for predicting ICU mortality was fair and was better than that of the APACHE II score (Fig. 3). A SOFA score of 8 and above and an APACHE II score of 21 and above were independently associated with an increased risk of hospital mortality (Table 3). Additionally, a SOFA score of 10 and above was an independent predictor of ICU mortality, in contrast to an APACHE II score of 19 and above, for which this role did not (Table 4).

In our study, the hospital mortality rate was lower than that of the MOSAICS I study (44.5%; 572/1285),(40) as well as the rates previously reported from LMICs in Southeast Asia, including Indonesia (68.3%; 41/60),(41) Thailand (42%; 263/627),(42) and Vietnam (61.0%; 75/123)(39). These findings may be because the diagnosis and treatment of sepsis have significantly changed over the previous ten years to increase patient survival in sepsis and septic shock.(1, 8, 13, 36, 38, 43, 44) However, our study showed rates for ICU and hospital mortality that were higher than rates reported in the international Extended Study on Prevalence of Infection in Intensive Care (EPIC III) study (28% [99/352] and 31.1% [110/352] in LMICs, 26.4% [821/3114] and 32.7% [1019/3114] in upper-middle-income countries [UMICs], and 21.3% [950/4470] and 28.5% [1275/4470] in HICs)(45). These variations might be because the EPIC III study included ICU-acquired infection rather than only sepsis.(45) Despite the distinct inclusion criteria, our median SOFA score at the time of ICU admission was comparable to that of the EPIC III study (7 points [IQR: 4–11] in LMICs/UMICs/HICs)(45). However, patients in our study received invasive organ support

treatments (i.e., MV and RRT) during ICU stays more frequently than those in the EPIC III study (54.4% [4377/8045] and 15.7% [1253/8045])(45). Previous studies showed that MV was a crucial predictor of mortality at any point throughout the ICU stay.(4, 35) Additionally, the utilization of RRT at any time during the ICU stay was also associated with a higher fatality rate.(4, 35, 46-48) Furthermore, *Acinetobacter baumannii* (17.9%, 45/252; Table S4 as shown in Supplementary file 3), one of the most harmful pathogens, was more frequently isolated from patients in the present study than those from the HIC cohort (4.4%; 137/3113) of the EPIC III study (45). The previous studies showed that *Acinetobacter baumannii* infection was often due to a lack of strict infection control bundles(49) and associated with an increased risk of death(50, 51). The fact that our proportions for ICU and hospital mortality were higher than those reported in the EPIC III study suggested that patients, pathogens, and clinical capacity to manage sepsis vary significantly between regions, particularly between HIC and LMIC settings.

In this study, we found a poor ability of both SOFA and APACHE II scores to predict hospital mortality (Fig. 2). However, with the SOFA score, the discrimination for predicting ICU mortality was fair, and it was better than those of the APACHE II score (Fig. 3). The APACHE scoring system is among the most widely used, of which there are four versions (APACHE I through IV scores). Although APACHE IV score is the most up-to-date version, some centres still use older versions including APACHE II score. In the present study, despite having a poor discriminatory ability for predicting hospital and ICU mortalities, an APACHE II score of 21 and above was independently associated with an increased risk of deaths in hospitals (Table 3). However, in contrast to a SOFA score of 10 and above, an APACHE II score of 19 and above was not an independent predictor of ICU mortality (Table 4). Previous studies revealed that the APACHE II score had a good prognostic value in

acutely ill or surgical patients (10, 11) but did not differentiate between the sterile and infected necrotizing pancreatitis and had a poor predictive value for the severity of acute pancreatitis at 24 hours (12).

In contrast, the SOFA score was proposed for patients with a suspected infection that an increase of 2 points or more could serve as clinical criteria for sepsis.(1) In ICU patients with suspected infection, discrimination of the SOFA score was fair for predicting hospital mortality, with an AUROC value of 0.74 (95% CI, 0.73 to 0.76; $P_{\text{AUROC}} < 0.001$), reported in the previously published studies.(1, 17) However, our study showed that the discriminatory ability of the SOFA score was poor for predicting hospital mortality (Fig. 2). This difference might be due to our SOFA score only calculated upon ICU admission, in contrast to the SOFA score in the previously published study that was calculated for the time window from 48 hours before to 24 hours after the onset of an infection, as well as on each calendar day.(17) This difference also might be because the burden and causes of sepsis and its management differ considerably between HIC and LMIC settings,(7, 35, 37) which might make the accuracy of critical illness severity scoring systems vary widely in the different countries, particularly between HICs and LMICs. However, our study revealed that the SOFA score had a fair discriminatory ability for predicting ICU mortality (Fig. 3). Moreover, a SOFA score of 8 and above and a score of 10 and above were independently associated with an increased risk of deaths in hospitals and ICUs, respectively (Tables 3 and 4). Overall, this study shows that both SOFA and APACHE II scores were worthwhile in predicting hospital and ICU mortalities in ICU patients with sepsis. However, because of having better discrimination for predicting ICU mortality, the SOFA was preferable to the APACHE II score in predicting mortality.

The present study's data from many centres, which contained few missing data points, was a benefit (Table S19 as shown in Supplementary file 3). The following are some drawbacks of the current study, though: *First*, since there isn't a national registry of ICUs to enable systematic recruitment of units, we used the snowball method to find suitable units, which may have resulted in the selection of centres with a greater interest in managing sepsis; as a result, our data are subject to selection bias and might not accurately reflect intensive care in all of Vietnam; *Second*, we did not create a protocol for microbiological investigations due to the study's real-world aspect. The data on point-of-care tests (such as lactate clearance) and life-sustaining therapies (such as fluid balance, steroid administration, and modalities of RRT and MV) were also missing since we primarily evaluated resources used in ICUs. Additionally, we decided not to gather information on antibiotic resistance and appropriateness to increase the practicality of performing the study in busy ICUs; *Thirdly*, the mixed-effects logistic regression model could not be used to predict the discrete outcome variables measured at two different times, i.e., inside and outside the ICU settings, due to our independent variables (e.g., SOFA score that was greater than or equal to the cut-off value), which might be associated with the primary outcome only measured upon ICU admission; *Finally*, even though the sample size was sufficient, the confidence interval was a little bit broad (6.03%), which may have an impact on the sample's normal distribution. Therefore, more studies with bigger sample sizes may be required to strengthen the findings.

CONCLUSIONS

Our cohort was a selected population of patients with sepsis admitted to the ICUs in Vietnam with a high mortality rate. The SOFA and APACHE II scores were worthwhile in predicting mortality among ICU patients with sepsis. However, due to better discrimination for

predicting ICU mortality, the SOFA score was preferable to the APACHE II score in predicting mortality.

Data availability statement

Data are available on reasonable request. Data are available on reasonable request to the authors.

Ethics statements

Patient consent for publication

Verbal informed consents were directly obtained from patients or, when unavailable, from family members at the ICUs and witnessed by the on-duty medical staff.

Ethics approval

The Scientific and Ethics Committees of Bach Mai Hospital approved this study (approval number: 2919/QĐ–BM; project code: BM-2017-883-89). We also obtained permission from the heads of institutions and departments of all participating hospitals (see Table S1, as shown in Supplementary file 3, for additional information concerning the hospitals' names) and their respective institutional review boards wherever available. The study was conducted according to the principles of the Declaration of Helsinki. In this non-intervention study, all collected information has received verbal informed consent from patients or, when unavailable, from family members at the ICUs, and witnessed by the on-duty medical staff. Written informed consent, however, was waived by the Bach Mai Hospital Scientific and Ethics Committees since it was not feasible to undergo such a methodical process of collection when the subject was comprised of an urgent situation in which a patient or a family member's condition was severe or life-threatening. Public notification of the study was

made by public posting. All data analyses were based upon datasets kept in password-protected systems, and all final presented data have been made anonymous.

Acknowledgments

We thank all ED and ICU staff of participating hospitals for their support with this study. We also thank the staff of the Faculty of Public Health at Thai Binh University of Medicine and Pharmacy for their support and statistical advice. Finally, we thank Miss Phuong Thi Tran from the Center for Emergency Medicine of Bach Mai Hospital, Hanoi, Vietnam, and Miss Mai Phuong Nguyen from St. Paul American School, Hanoi, Vietnam, for their support with this study.

FIGURE LEGEND

Figure 1. Flowchart of the study design, patient enrolment and follow-up (Abbreviations: ICU, intensive care unit; “**discharged to die**”, defined as the patients were in grave condition or dying and were classified with deaths in the ICU at the time of discharge).

Figure 2. Comparisons of the AUROCs: Comparing the overall diagnostic performance of the SOFA score (AUROC: 0.688 [95% CI: 0.618–0.758]; cut-off value ≥ 7.5 ; sensitivity: 64.4%; specificity: 69.8%; $P_{\text{AUROC}} < 0.001$) and the APACHE II score (AUROC: 0.689 [95% CI: 0.622–0.756]; cut-off value ≥ 20.5 ; sensitivity: 61.4%; specificity: 71.8%; $P_{\text{AUROC}} < 0.001$) for predicting hospital mortality in ICU patients with sepsis (Abbreviations: **APACHE II**: Acute Physiology and Chronic Health Evaluation II score; **AUROC**: areas under the receiver operating characteristic curve; **CI**: confidence interval; **ICU**: intensive care unit; **ROC**: receiver operator characteristic curve; **SOFA**: Sequential Organ Failure Assessment score).

Figure 3. Comparisons of the AUROCs: Comparing the overall diagnostic performance of the SOFA score (AUROC: 0.713 [95% CI: 0.643–0.783]; cut-off value ≥ 9.5 ; sensitivity: 53.6%; specificity: 80.1%; $P_{\text{AUROC}} < 0.001$) and the APACHE II score (AUROC: 0.672 [95%

CI: 0.603–0.742]; cut-off value ≥ 18.5 ; sensitivity: 69.0%; specificity: 60.8%; $P_{\text{AUROC}} < 0.001$) for predicting ICU mortality in ICU patients with sepsis (Abbreviations: **APACHE II**: Acute Physiology and Chronic Health Evaluation II score; **AUROC**: areas under the receiver operating characteristic curve; **CI**: confidence interval; **ICU**: intensive care unit; **ROC**: receiver operator characteristic curve; **SOFA**: Sequential Organ Failure Assessment score).

Day of the 1515 patient enrolment from 15 eligible adult ICUs on the 4 days identified in the year (i.e., 9th January, 7th April, 3rd July, and 9th October, 2007)

Excluded 1263 ineligible patients

- < 18 years
- ineligible for sepsis
- hospital transferred/discharged alive from 00:00 hour to 23:59 hour of the study days

1512 patients eligible for analysis

30 patients admitted on day of patient enrolment for sepsis and stayed beyond day of patient enrolment

2 patients admitted on day of patient enrolment for sepsis and died/discharged to die on same day

1280 patients admitted before day of patient enrolment for sepsis but still in ICU on day of patient enrolment

Data collection of demographics, clinical parameters and investigations

Data collection on sepsis bundle and ICU resource utilization

Data collection of patient's outcomes
84 patients died in ICU stay
191 patients died in hospital stay

ROC Curve
