Running Title: Protection from Masking Wanes during Omicron

Abstract (up to 50 words, unstructured format)

We assessed the association between self-reported mask use during non-household interactions and COVID-19 infection during three pandemic periods. Odds of infection for those who did not always compared to those who always wore a mask was 66% higher during pre-Delta, 53% higher during Delta, declining to 16% higher during Omicron.

Key words: COVID-19, mask use

Introduction

Wearing a facemask has been a primary public health method to reduce SARS-CoV-2 transmission throughout the pandemic.^{1,2,3} However, how well masks conveyed protection during each variant wave, including the most recent Omicron wave, has yet to be evaluated. Using prospectively collected data from the North Carolina COVID-19 Community Research Partnership (CCRP), we assessed the association between self-reported mask use when interacting with others outside the household and risk of COVID-19 infection during three periods of the pandemic.

Methods

The NC CCRP⁴ is a prospective, multi-site cohort COVID-19 syndromic surveillance study of a convenience sample of participants enrolled primarily through direct email outreach at six NC healthcare systems from April 2020 through June 2021 (<http://www.covid19communitystudy.org/>). Data were collected via a secure, HIPAA-compliant, online platform through March 2022. All participants provided informed consent, and Institutional Review Board (IRB) approval was provided by the Wake Forest School of Medicine. We performed a nested case-control analysis within the study cohort to compare self-reported cases to controls who never self-reported a positive test for SARS-CoV-2 infection. For this report, eligible participants were ≥ 18 years, completed daily syndromic surveillance surveys, did not participate in a vaccine trial, and did not self-report prior COVID-19 infection at enrollment (**Supplemental Figure 1**). Demographic data and healthcare worker status were collected at enrollment. Daily online email or text surveys asked about COVID-19 symptoms, test results, vaccination, and risk behavior. Not wearing a mask was defined as responding “no” at least once in the ten days preceding the match date to the daily survey question, “In the last 24 hours, have you worn a face mask or face covering every time you interacted with others (not in your household) within a distance of less than 6 feet?” We defined SARS-CoV-2 vaccination using participant self-report and categorized participants into three categories: at least 14 days after receiving second of two doses of either the Pfizer BioNTech BNT162b2 or Moderna mRNA-1273 vaccine, receiving at least one dose of either mRNA vaccine or unvaccinated. Participants who reported receiving a non-mRNA vaccine or had an undetermined vaccine status were excluded.

We matched up to 10 controls to each case on calendar time of first self-reported positive test. Case participants self-reported at least one infection (positive SARS-CoV-2 antigen or nucleic acid amplification test) during study follow-up. To address multiple eligible survey entries available for matching per control, we used an optimal matching algorithm maximizing the cases included in the analysis.⁵ The number of controls per case ranged from 1 to 10 with a median of 7. Descriptive statistics are presented as absolute and relative frequencies with p-values from unadjusted Pearson’s chi-squared tests and standardized mean differences. Conditional logistic regression models of COVID-19 infection were adjusted for enrollment site, age group, race/ethnicity, county population density (urban/suburban/rural), healthcare worker occupation, vaccination status, and recent known exposure to COVID-19. Covariates in the multivariable model were selected a-priori. After assessing whether there was an interaction between variant predominant period and mask use, we evaluated three periods during the pandemic: Pre-Delta (July 1 2020 – June 30, 2021), Delta (July 1, 2021 – November 30, 2021), and Omicron (December 1, 2021 – February 28, 2022) predominance. Analyses were performed using R (V.4.0.3, R Foundation for Statistical Computing).

Results

Of the 3,901 cases and 27,813 date-matched controls, participants were majority female (71.5% of cases, 68.6% of controls) and non-Hispanic white (89.1% of cases and 87.5% of controls). Healthcare worker occupation was common (35.4% of cases and 26.8% of controls) (**Supplemental Table 1**). Over half of the cases and controls were matched ≥ 14 days after a second mRNA vaccine dose (53.7% of cases and 55.7% of controls). About a

quarter of participants (25.8% of cases and 27.9% of controls) had at least one comorbidity. The pre-Delta predominant period accounted for 42.5% of cases, compared to 17.1% during the Delta-predominant period and 40.5% during the Omicron-predominant period.

The daily survey response rate in the ten days preceding the match date was 73.1% for cases and 65.3% for controls. Overall, reporting not wearing a facemask when interacting with others outside the household was more prominent among cases prior to the index date (date self-reported positive test) and less prominent after the index date. Approximately 42.5% of cases and 36.3% of controls responded at least once that they did not wear a mask when interacting with others in the 10 days preceding the match date (**Supplemental Table 2**). Mask wearing behavior varied by period in the pandemic (**Figure 1**). Overall, not wearing a mask increased between the pre-Delta and Delta period, then decreasing slightly during the Omicron period. During the pre-Delta period, 28.5% of cases and 19.4% of controls reported at least one day in the 10 days preceding the index date not wearing a mask compared to 61.5% of cases and 55.1% of controls during the Delta period, and 50.2% of cases and 47.5% of controls during the Omicron-predominant period. Over half of the cases (54.1%) reported a known exposure to someone who recently tested positive for COVID-19 in the ten days preceding the index date compared to only 9.3% of controls.

The association between mask use and SARS-CoV-2 infection varied by period (p-interaction <0.001). During the pre-Delta predominant period, the odds of SARS-CoV-2 was 66% higher (adjusted odds ratio (aOR)=1.66, 95% CI=1.43 – 1.91) among participants reporting at least one day not wearing a mask in the 10 days preceding the index date compared to those who reported no days (**Supplemental Table 3**). During the Delta-predominant period, the results were similar (aOR=1.53, 95% CI=1.23 – 1.89). This association was attenuated but remained significant during the Omicron-predominant period, where the odds of SARS-CoV-2 was 16% higher (aOR=1.16, 95% CI=1.03 – 1.32) for those reporting at least one day not wearing a mask compared with those who reported no days not wearing a mask.

Discussion

In this community-based observational study, we found that any days not wearing a mask was associated with increased odds of SARS-CoV-2 infection after adjusting for demographics and recent known exposure. While the effect of not wearing a mask on disease transmission during non-household interactions remained significant during the entire study period, we observed a decrease in this association during the Omicron-predominant period. This variation was seen against decreasing overall mask use across the three periods.

Our findings during the pre-Delta and Delta predominant periods are consistent with previous studies suggesting that wearing a mask consistently is related to lowered odds of testing positive.² To the best of our knowledge, this is the first study to extend into the Omicron predominant period and compare the protectiveness of masks.

Strengths of this study include prospectively collected data over two years on a large number of participants throughout the pandemic, and therefore is not subject to recall bias following infection. However, our findings may be limited by selection and reporting bias and may not be generalizable to other geographic regions. Other limitations include the use of self-report to determine mask use and a lack of nuance in the masking question to allow for improper use (e.g., not covering mouth or nose), type of mask (e.g., cloth, surgical or KN95/N95 mask), duration of use, and frequency and duration of interactions.

Our results suggest decreased protection for the wearer from masks during the Omicron-predominant wave. These findings may also be explained by more frequent exposures outside of one's household later in the pandemic, increased transmissibility of the Omicron variant, high rates of vaccination and increasing population immunity during the Omicron-predominant period, and a decrease in mask wearing as guidance for vaccinated individuals evolved over time.^{6,7} While masking continues to be one of the valuable tools to decrease risk of

COVID-19 infection, the level of protection for an individual wearer appears to have declined during the Omicron phase of the pandemic. Recent studies have suggested that facemasks have the potential to not only decrease odds of infection but also reduce severity of COVID-19.⁸ Future research may focus on not only odds of infection but also symptoms and severity of disease associated with mask wearing.

Figure 1. Proportion of Participants Responding to Daily Survey that they did not wear a face mask or face covering every time the interacted with others preceding and following match date (Day 0), by variant-predominant period
