A global agreement in Central Nervous System (CNS) tumors classification is essential in order to decide treatment correctly, predict prognosis, evaluate treatment response, compare outcomes, and select adequate patients for clinical trials at international level.

The last update of the World Health Organization (WHO) of CNS tumor classification and grading 2021 considered for the first time glioblastoma IDH-wildtype and astrocytoma IDH-mutant grade 4 as different tumors. IDH mutation produces a metabolic reprogramming of tumor cells, thus affecting the processes of hypoxia and vascularity. The differences in the aggressiveness of these gliomas, which affect patient survival, are evident, with a clear advantage for those patients who present IDH mutated tumors.

Despite the clinical relevance of IDH mutation, current protocols do not include full sequencing for every patient. Alternative biomarkers could be useful and complementary to get a more reliable classification. In this sense, MRI-perfusion biomarkers, such as relative cerebral blood and flow (rCBV and rCBF), could be key because they are non-invasive, can be used from the presurgical moment, and do not suppose additional economical or effort costs.

The main purpose of this work is to evaluate and validate the association between MRI-DSC biomarkers and IDH mutation status in high-grade astrocytomas. In addition, to get a deeper understanding of the vascular differences, we aim to study the transcriptomic bases of these vascular differences between these two high-grade astrocytomas.

NOTE: This preprint reports new research that has not been certified by peer review and should not be used to guide clinical practice.
Introduction

Astrocytomas grade 4 includes two different tumors since 2016, when the CNS tumors classification and grading of the WHO incorporated new entities according to both histology and molecular features\(^1\,^2\). This difference is maintained in the new WHO of CNS 2021\(^1\), and in addition, it is accentuated, having also changed its nomenclature to glioblastoma IDH-wildtype and astrocytoma IDH-mutant grade 4 (instead of only glioblastoma). Glioblastoma IDH-wildtype represents about 95% of astrocytomas grade 4 and predominates in patients over 55 years of age. Astrocytoma IDH-mutant grade 4 (about 5% of cases) is more frequent in younger patients or in those with a history of prior lower grade diffuse glioma\(^1\,^2\,^3\).

Relevant differences are found between these two astrocytoma types at the clinical level, since they cause different patient survival rates\(^3\,^6\) as well as distinct therapy responses\(^7\,^8\). Therefore, it is evident that an early-stage classification considering the IDH mutation is necessary to get an adequate prognostic evaluation and a more personalized treatment of patients with astrocytomas grade 4.

Despite its important role, the definition of full IDH evaluation can differ according to patient age\(^2\), clinical protocols, and centers. The absence of R132H IDH1 and IDH2 mutations in astrocytomas from patients over about 55 years old suggests that sequencing may not be needed in the setting of negative R132H IDH1 immunohistochemistry in those patients. Since protocols do not include full sequencing for every patient, alternative biomarkers could be useful and complementary to get a more reliable classification. In this sense, MRI-based methodologies could be key because they are non-invasive, could be used from the presurgical moment, and do not suppose additional economical or effort costs.

In 2020, Hao Wu et al.\(^10\) evaluated the potential clinical impact of the Hemodynamic Tissue Signature (HTS) method\(^11\) for predicting IDH mutation status in patients with glioma tumors. They analyzed the association between the relative cerebral blood volume (rCBV) at the high angiogenic tumor (HAT) habitat and the IDH mutation status. A significantly decreased rCBV for the IDH-mutant group was found. They concluded that “the HTS method was proven to have high prediction capabilities for IDH mutation status in high-grade glioma patients”. Despite the great interest in these results, it only includes 25 patients with astrocytoma grade 4. In addition, the molecular basis of these vascular differences between these two high-grade tumors is still unsolved.

The main purpose of this work is to evaluate and validate the association between MRI-DSC biomarkers and IDH mutation status in high-grade astrocytomas. In addition, to get a deeper understanding of the vascular differences, we aim to study the transcriptomic bases of these vascular differences between these two high-grade astrocytomas.
Material and Methods

Study cohorts

Patient cohort with MRI data

The study cohort includes 299 patients with MRI data, 16 of whom presented astrocytoma IDH-mutant grade 4, and the rest 283 presented glioblastoma IDH-wildtype. To collect this cohort, both public (35 patients from TCGA-GBM, 19 patients from Ivy GAP, and 10 from CPTAC-3) and private datasets (108 patients from MTS4UP dataset, 20 from GEINO-mol dataset, and 107 from GLIOCAT dataset) were used. Public datasets are available in The Cancer Imaging Archive (TCIA): https://www.cancerimagingarchive.net/. Private data are available upon reasonable request to the authors. Ethics committee of Universitat Politècnica de València gave ethical approval for this work.

Public dataset with RNAseq data

To analyze differences in gene expression between these two types of astrocytoma, two public datasets have been used, including 99 patients from CPTAC3 and 151 patients from TCGA-GBM.

MRI data

Presurgical MRI studies were collected from all the included datasets, including pre- and post-gadolinium T1-weighted, T2-weighted, FLAIR, and DSC T2*-weighted perfusion sequences obtained by the standard of care protocols using 1.5 or 3.0-T.

MRI processing and perfusion markers calculation

To process the MRIs and to calculate the imaging vascular biomarkers, we used the HTS method, included in the ONCOhabitats site (www.oncohabitats.upv.es)\textsuperscript{11-13}. The HTS method is illustrated in figure 1 and includes the following stages:

a. Preprocessing. In this stage, common MRI artifacts such as magnetic field inhomogeneities and noise, multimodal registration, brain extraction, or motion correction are corrected.

b. Glioma segmentation. A state-of-the-art deep learning 3D convolutional neural network is implemented to segment the enhancing tumor, the edema, and the necrotic tissue. It is based on the directional class adaptive spatially varying finite mixture model (DCA-SVFMM), which is a clustering algorithm that combines Gaussian mixture modeling with continuous Markov random fields to make use of the self-similarity and local redundancy of the images. This methodology uses the unenhanced and GBCA-
enhanced T1-weighted sequences, the T2-weighted sequence, and the fluid-attenuated inversion-recovery T2-weighted sequence combined with atlas-based prior knowledge of healthy tissues to delineate the regions.

c. **DSC perfusion quantification.** During this stage, the hemodynamic maps derived from the DSC perfusion sequence are calculated, including Rcbv, rCBF, MTT, and K2 permeability. All perfusion maps are normalized against contralateral unaffected white matter volume to achieve consistency and comparability across different datasets. The normalization is performed automatically by a convolutional neural network, which detects the contralateral unaffected white matter region with 90% accuracy. To ensure a correct perfusion quantification and to avoid under- and over-estimation of perfusion marker, DSC perfusion quantification includes a correction for contrast agent leakage effects. The HTS method implements the Boxerman leakage-correction method for T1- and T2-leakage effects, as well as gamma-variate fitting to remove the extravasation phase and second pass of the contrast bolus.

d. **Hemodynamic Tissue Signature (HTS) habitats.** In this final stage, an automated unsupervised segmentation algorithm performs the detection of the four vascular habitats within the tumor and edema. Each delineated habitat presents its specific hemodynamic behavior. They are named as: the High Angiogenic Tumor (HAT) habitat, the Low Angiogenic Tumor (LAT) habitat, the Infiltrated Peripheral Edema (IPE) habitat, and the Vasogenic Peripheral Edema (VPE) habitat. HTS habitats are delineated using a DCA-SVFFM structured clustering of rCBV and rCBF maps. The clustering includes two stages: (I) a two-class clustering of the whole enhancing tumor and edema regions and (II) a two-class clustering performed by using only the rCBV and rCBF data within the regions obtained in the first stage. To ensure the reproducibility of the HTS, both stages were initialized with a deterministic seed method.

**Figure 1.** The hemodynamic Tissue Signature (HTS) method, includes the four stages: (1) preprocessing, (2) glioma segmentation in classical tissues: active tumor, edema, and necrosis, (3)
DSC perfusion quantification, and (4) HTS habitats: High Angiogenic Tumor (HAT), Low Angiogenic Tumor (LAT), Infiltrated Peripheral Edema (IPE), and Vasogenic Peripheral Edema (VPE).

RNA data

Data Download and Normalization

For both datasets, we retrieved the HT-Seq mRNA read counts from the TCGA database. Samples without IDH status information were filtered out to define two experimental groups: IDH-mutant and IDH-wildtype. Read counts were filtered by expression, removing genes with low counts across all samples. Normalization factors were calculated for each dataset using the Trimmed Mean of M-values (TMM) method\textsuperscript{15}.

Differential Gene Expression Analysis

We determined the Differential expressed genes (DEGs) in both datasets by fitting a quasi-likelihood negative binomial generalized log-linear model, implemented in the edgeR R package\textsuperscript{16}. P values were corrected using the Benjamini-Hochberg procedure to control type I errors when conducting multiple comparisons. Genes having an adjusted p-value lower than 0.05 and an absolute value of log Fold-Change greater than 1 were considered as differentially expressed.

Statistical Analyses

Study cohort description

To evaluate the differences in survival between both groups of patients, Kaplan Meier analyses and Log Rank test were performed. The relationships between demographic and clinical variables, and overall survival (OS) were assessed using independent uniparametric Cox regression models.

Correlation between MRI-DSC biomarkers calculated at vascular habitats with IDH mutation

We evaluated the significant correlation between each MRI-DSC biomarker with OS to select the optimal biomarkers to find differences among astrocytoma types.

Differences in the imaging vascular biomarkers between IDH-wildtype glioblastoma and IDH-mutant astrocytoma grade 4 were assessed with Mann Whitney U test, as well boxplots were performed to illustrate differences.

Differences in transcriptome between high-grade astrocytoma types

Results from Differential Expression Analysis were functionally annotated using the Biological Processes ontology from the Gene Ontology database\textsuperscript{125,126}. First, we selected the GO terms related to vascular processes by matching a list of vascular key terms (table
S1 of Supporting Material). Then, we selected all genes mapping with these matched GO terms as our vascular genes set. Most significant vascular and non-vascular DEGs were plotted in heatmaps to illustrate the differences between expression profiles across experimental groups.

Finally, we assessed Overall functional differences between astrocytoma types by performing a Gene Set Enrichment Analysis (GSEA) on Differential Expression Analysis results using the fgsea R package17. Genes were pre-ranked according to their log fold-change values. Gene sets with an adjusted p-value < 0.05 were considered significant.

Results
Detection of relevant prognostic demographic and clinical variables

We analyzed the correlation between OS with the following demographic and clinical characteristics: age, sex, tumor resection type, tumor location (hemisphere), IDH mutation, and MGMT methylation. Results are included in figure 2A, resulting in the IDH mutation as the variable most correlated with longer survival rates (with the lowest hazard ratio), followed by methylated MGMT and total tumor resection.

Cohorts’ description

Proportions of each type of astrocytoma in this study dataset are coherent with previously published literature10,11,118, representing the population with IDH-wildtype glioblastoma a 95% of the entire cohort (figure 2B). In addition, the number of patients from each dataset with IDH-mutant astrocytoma and IDH-wildtype glioblastoma were compared, showing these proportions differences among datasets (figure 2C).

Differences in OS between these two groups were studied, demonstrating significantly longer survival times for the group of patients with IDH-mutant astrocytoma grade 4 (p = 0.001, Log-rank test). Kaplan Meier curves are included in figure 2D, illustrating a median difference in OS of 267 days among the two populations.
Figure 2. A) Scatter plot with the correlation between the main demographic and clinical characteristics and overall survival. B) Proportion of patients of the studied cohort with IDH-mutant astrocytoma and IDH-wildtype glioblastoma. C) Number of patients from each dataset with MRI data. D) Kaplan Meier curves showing the survival differences between patients with astrocytoma IDH-mutant grade 4 (n = 16) and glioblastoma IDH-wildtype (n = 287).
Differences in the main demographic, clinical, and molecular features between the two populations were analyzed and the results are included in table 1.

**Table 1.** Demographic, clinical, and molecular features for the cohort with IDH-mutant astrocytoma (n = 16) and for the cohort with IDH-wildtype glioblastoma (n = 287). P-values resulting from the Mann-Whitney test are also included.

Only the median age of diagnosis was significantly different between groups, being lower for the group of patients with astrocytoma IDH-mutant grade 4 (49 vs 60 years old).

**Correlation between imaging vascular biomarkers and overall survival**

rCBV and rCBF markers at each vascular habitat (HAT, LAT, IPE, and VPE) and for each metric (mean, median, and maximum) were calculated, resulting in 24 markers. We studied the potential prognostic capacity of these markers, analyzing their correlation with IDH mutational status.

Figure 3 shows the correlation coefficient and the significance of each MRI-DSC biomarker with overall survival. We can see that the 12 markers related to the HAT and LAT habitats are the most significantly correlated (p<0.05), but only the rCBV markers yield a coefficient higher than 0.2. The selected markers to develop the following analyses were HAT-rCBV\textsubscript{mean}, HAT-rCBV\textsubscript{median}, HAT-rCBV\textsubscript{max}, LAT-rCBV\textsubscript{mean}, LAT-rCBV\textsubscript{median} and LAT-rCBV\textsubscript{max}.
Figure 3. Scatter plot with the correlation results (Spearman coefficients and significance) between MRI-DSC biomarkers and overall survival for the entire cohort (n = 299). Circle markers show rCBV and triangles show the rCBF. Each habitat is represented with a color, HAT in red, LAT in yellow, IPE in green, and VPE in blue, and different metrics are also indicated (mean, median and maximum).

Significant differences (Mann Whitney, p<0.05) in the selected imaging vascular biomarkers between IDH-mutant astrocytomas grade 4 and IDH-wildtype glioblastomas were found and are illustrated in figure 4. For all the selected MRI-DSC biomarkers, the median value and the minimum and maximum range were higher for the IDH-wildtype glioblastoma group, suggesting significantly higher vascularity for these tumors in comparison with IDH-mutant astrocytomas grade 4. Table S2 of Supporting Material includes the exact values of each biomarker for the group of IDH-wildtype glioblastoma and IDH-mutant astrocytoma grade 4.
Figure 4. Boxplot showing differences in perfusion between glioblastomas IDH-wildtype and astrocytomas IDH-mutant grade 4.

**Distinct transcriptome between IDH-wildtype glioblastoma and IDH-mutant astrocytoma grade 4**

Differential expression analysis revealed considerable transcriptomic variations between glioblastoma IDH-wildtype and astrocytoma IDH-mutant grade 4. The total number of significant DEGs (adjusted p-value < 0.05 and absolute log Fold-Change > 1) was consistent across datasets (2568 and 2056 DEGs from CPTAC and TCGA, respectively, with an intersection of 879 DEGs).

We detected 1313 (CPTAC) and 1262 (TCGA) overexpressed genes in the IDH-wildtype group. A considerable fraction of these DEGs were considered part of the “vascular” functional gene set (143 and 123, respectively, with an intersection of 75 DEGs).

Also, we determined that a total of 1345 (CPTAC) and 794 (TCGA) genes were overexpressed in the IDH-mutant group. A total of 30 and 37 DEGs, respectively, were labeled as “vascular” genes, having in common a group of 11 DEGs.

Figure 5 includes the heatmaps showing different gene expressions between glioblastoma IDH-wildtype and astrocytoma IDH-mutant grade 4 performed with two public datasets. Vascular genes are marked in different colors.
Figure 5. Heatmaps showing different gene expressions between IDH-wildtype glioblastoma and IDH-mutant astrocytoma grade 4 were performed with two public datasets: A) CPTAC3 (n = 93, and 6 respectively) and B) TCGA-GBM (n = 140, and 11 respectively)
All significant DEGs, labeled as vascular or nonvascular, are included in the supplementary table S3. This table also contains the adjusted p-values and the log Fold Change values for each gene.

GSEA results showed significant differences between the two groups at the biological processes level. On the one hand, a total of 169 (CPTAC) and 39 (TCGA) GO terms showed significant overrepresentation in IDH-wildtype Glioblastomas. A core subset of 33 GO terms was present in both sets of significant functions.

On the other hand, we only detected 1 (CPTAC), and 3 (TCGA) significantly overrepresented GO terms in IDH-mutated Astrocytomas. There was not any coincident function between sets.

Discussion
With this study we have demonstrated that IDH-wildtype glioblastoma and IDH-mutant astrocytoma grade 4 present different vascular patterns both in high- and low-angiogenic tumor habitats, defined by the automatic ONCOhabitats method. These differences can be detected using MRI-DSC biomarkers, such as rCBV and rCBF calculated from the presurgical stage, since they are correlated with the presence of the IDH mutation. These results are obtained with a multicenter cohort of 299 patients and validate those found in a previous study.

The association between tumor and edema vascularity and OS has been previously analyzed in literature. There is a consensus that higher values of vascularity, measured by DSC perfusion biomarkers, result in shorter survival times. These important differences in survival may be due in part to different vascular behavior, resulting in quicker progression and greater aggressiveness of IDH-wildtype glioblastomas. With this work, we have validated this hypothesis, demonstrating significantly higher rCBV values for IDH-wildtype glioblastomas. The clinical relevance of this finding is that opens the possibility to use the MRI-DSC biomarkers as complementary tools to support the first diagnosis made by the radiologist from the presurgical stage.

In addition, to acquire a deeper understanding of vascular differences between these two high-grade astrocytomas, we analyzed gene expression patterns of two public datasets that include RNAseq data. We focused on analyzing genes related to vascular processes and structures. We found that 75 genes related to vascularity were up-regulated in both datasets for the group of IDH-wildtype glioblastoma, versus only 11 vascular genes up-regulated in the group of IDH-mutant astrocytomas grade 4. This finding supports our hypothesis, that stronger vascular processes occur during the establishment and progression of IDH-wildtype tumors.
In glioblastomas IDH-wildtype, we found overexpression of several genes previously reported as associated with vascular remodeling and arterial abnormalities in high-grade gliomas. Some of these genes are EGF-containing fibulin-like extracellular matrix protein 2 (EFEMP2), solute carrier family 2 member 10 (SLC2A10), midkine (MDK), and transmembrane BAX inhibitor motif-containing 1 (TMBIM1). They also have been proven as associated with poor progression, which seems coherent since a higher vascular supply allows quicker tumor progression.

On the other hand, there were 11 vascular genes overexpressed in astrocytomas IDH-mutated grade 4 compared with glioblastomas IDH-wildtype. We can remark on the relevance of bone morphogenetic protein 2 (BMP2), which has been previously defined as relevant for prognosis estimation, since the higher the expression of BMP2, the better the prognosis of patients. In addition, we found an overexpression in STOX1, which was previously associated with younger patients and with gliomas of lower grades and less aggressive. The correlation of higher expression of these genes with the presence of IDH mutation can be due to the metabolic reprogramming that suffers tumor cells with this alteration.

Conclusions

In conclusion, we have validated the association between the IDH mutation with tumor vascularity, measured by DSC perfusion biomarkers at HAT and LAT habitats. Astrocytomas IDH-mutant grade 4 present lower rCBV and rCBF, and longer survival times, which can be partly explained by a slower tumor progression, due to less vascularity.

We have assessed on the potential relevance of specific genes overexpressed in glioblastomas IDH-wildtype, such as EFEMP2, SLC2A10, MDK, and TMBIM1, and in IDH-mutant astrocytomas grade 4, such as BMP2 and STOX1. Although it is needed deep analyses, these genes can be proposed as targets for specific novel therapies for each type of high-grade astrocytoma.

This constitutes the first study analyzing vascular differences both at MRI and transcriptomic levels between IDH-wildtype glioblastoma and IDH-mutant astrocytoma grade 4. We propose DSC biomarkers automatically calculated with the ONCOhabitats method as useful to estimate the IDH mutation status in astrocytomas grade 4 from the presurgical stage. Moreover, we suggest the key role of specific genes overexpressed in glioblastomas IDH-wildtype as determinant for presenting stronger vascularity; and the clinical relevance of BMP2 and STOX1 for astrocytomas IDH-mutant grade 4.
