Abstract

Background: HIV infection is associated with more rapid progression of some comorbidities.

This study assessed the impact of HIV-infection where the presentation and outcome of HCC was different in persons living with HIV (PLWH) compared to those without HIV infection.

Methods: HCC patients attending the Mulago National Referral Hospital in Uganda were enrolled into a natural history study of HCC between March 2015 and February 2019. Standardized methods were used to collect clinical, ultrasound and laboratory data at enrolment. HCC cases were confirmed based on a combination of clinical, ultrasound, tumor marker and pathology data. Follow-up contact was made at one, three, six, and twelve months post-enrolment to determine vital status. Symptoms and signs at diagnosis and subsequent survival were compared by HIV status. Kaplan Meier curves were used to assess HCC survival.

Results: Of 441 persons with HCC, 383 (87.0%) died within 12 months following HCC diagnosis. The median (IQR) survival was 42 (20, 106) days. The most commonly reported symptom clusters were pain (80%), gastrointestinal symptoms (28%) and anorexia / cachexia (10%), and no differences were detected in these presenting symptoms (nor most other initial findings) in the 79 (18%) PLWH compared to those without HIV. After adjusting for baseline demographic and clinical characteristics, HIV infection was associated with increased mortality but only among those with severe HIV-associated immunosuppression (CD4 count <200 cells per cubic milliliter), aHR (95% C) = 2.12 (1.23-3.53), p=0.004, and not among PLWH with ≥200 CD4 cells per cubic milliliter, aHR (95% C) = 1.15 (0.82-1.60), p=0.417.

Conclusion: Among relatively young Ugandans, HCC is a devastating disease with rapid mortality that is especially rapid among PLWH. HIV was associated with slightly higher mortality, notably among PLWH with lower CD4 cell counts. As a substantial majority of PLWH diagnosed with HCC were engaged in HIV care, further investigation should determine the

effectiveness of incorporating screening and early identification of HCC among high-risk individuals into existing HIV care programs. Concurrent with growing access to curative localized treatment for HCC in sub-Saharan Africa, leveraging HIV care infrastructure affords opportunities for earlier HCC intervention.

Keywords: hepatocellular carcinoma (HCC), mortality, Human Immunodeficiency Virus, sub-Saharan Africa

1 Introduction

2 Hepatocellular carcinoma (HCC) is the sixth most commonly diagnosed cancer and the
3 third leading cause of cancer death worldwide.¹ It is one of the least curable malignancies with
4 the number of new cases reported (905,677) approximating the number of deaths (830,180)
5 worldwide in 2020.^{1,2} HCC has the amongst the shortest survival time of any cancer,³ with an
6 even poorer prognosis among patients in lower-income countries which disproportionately bear
7 a higher burden of primary risk factors and of HCC.⁴ With the advent of effective combination
8 antiretroviral therapy (cART), people living with HIV infection (PLWH) have had dramatically
9 improved survival.^{5,6} While the rates of many AIDS-defining cancers have declined, non-AIDS
10 defining cancers including HCC are increasing in incidence.^{7,8} Previous studies looking at
11 incidence of HCC during the cART-era have shown an increase in HCC incidence in HIV-
12 infected persons, compared with the general population.^{9,10} Trends in North America have
13 demonstrated increased HCC incidence rates among PLWH coinciding with increased uptake
14 and efficacy of ART.¹¹ These data raise the question of the impact that this transition may have
15 in sub-Saharan Africa which accounts for more than 70% of the global HIV burden, where
16 cART is being widely rolled out and where the median survival for PLWH is increasing.¹²
17 Further, compared to more developed regions, sub-Saharan Africa has higher underlying HCC
18 incidence rates and greater burden of HCC risk factors (e.g., endemic hepatitis B virus (HBV)
19 infection, broad aflatoxin exposure) which may substantially influence the burden of HCC among
20 PLWH in Africa.

21 In more developed regions, PLWH with cancer experienced higher cancer-specific
22 mortality than HIV-uninfected patients, independent of cancer stage or receipt of cancer
23 treatment.¹³ General estimates of cancer survival in Uganda have shown a poor prognosis for
24 patients with a 2.3% 5-year survival rate.¹⁴ Earlier studies conducted on a cohort of Ugandan
25 HCC patients showed a median survival of 1 month among untreated patients.¹⁵ However, these

26 data are over 30 years old and predate the current situation of substantial HIV prevalence of
27 6.5%¹⁶ among adults. As a result, there are a paucity of data in Uganda on the impact of HIV
28 infection on the clinical presentation and subsequent survival of HCC cases.

29 The objective of this study was therefore to analyze data on the clinical presentation at HCC
30 diagnosis and characterize survival in a contemporary cohort of patients diagnosed with HCC in
31 Uganda, emphasizing any differences attributable to HIV infection.

32 **Methods**

33 Study population:

34 As part of a hospital-based case-control study, HCC patients were prospectively
35 recruited from the gastrointestinal and oncology wards of Mulago National Referral Hospital in
36 Kampala, Uganda between March 2015 and February 2019. Potential participants were deemed
37 eligible if they were 12 years of age or older and spoke and comprehended English or Luganda,
38 the languages in which consenting materials were administered. All adult participants provided
39 written informed consent; assent and parental/guardian consent were obtained prior to enrolling
40 12-17-year-old individuals. The study was approved by the Makerere University School of
41 Medicine Research and Ethics committee, Uganda National Council for Science and
42 Technology and the Johns Hopkins University Institutional Review Board.

43 Study procedures:

44 All enrolled participants underwent standardized interview, clinical, and ultrasound
45 examination. Questionnaires were administered by trained staff and collected data on socio-
46 demographic, behavioral and clinical factors, and the duration and type of presenting symptoms.
47 Patients self-reported their initial symptom(s) and indicated their duration. Further, interviewers
48 assessed symptoms commonly occurring in HCC at time of enrollment utilizing a standardized
49 questionnaire previously used in HCC studies from Africa.^{17,18} Clinical examination assessed

50 physical signs reflective of HCC or advanced liver disease including jaundice, wasting,
51 hepatosplenomegaly, abdominal tenderness, ascites, collateral veins, hepatic bruit and
52 asterixis. These data were collected by study physicians who underwent standardized training
53 using uniform data collection instruments.

54 Laboratory testing was performed at a single laboratory (Makerere University- Johns
55 Hopkins University Core Laboratory; Kampala, Uganda) for hepatitis B surface antigen (HBsAg),
56 anti-hepatitis B core antibodies (anti-HBc), anti-hepatitis B surface antibodies (anti-HBs), anti-
57 hepatitis C antibodies (anti-HCV), HIV antibody, alpha-fetoprotein (AFP), alanine
58 aminotransferase (ALT), aspartate aminotransferase (AST), total bilirubin, international
59 normalized ratio (INR), and a complete blood cell count. Urine was tested for circulating
60 cathodic antigen (CCA) for diagnosis of active *Schistosomiasis* infection.

61 Ultrasound was performed by trained radiographers/radiologists with data collected on a
62 standardized ultrasound form, as previously described.^{17,19} For this analysis, characterization of
63 tumor number and size were incorporated.

64 HCC case definition: Participants with a clinical presentation compatible with HCC were
65 confirmed by a standardized ultrasound examination showing space-occupying lesions with
66 either an AFP level ≥ 100 ng/ml or liver biopsy documenting histologically-confirmed HCC. Study
67 staff facilitated the completion of diagnostic assessments and almost uniformly, the initial
68 diagnostic confirmation of HCC was concurrent with study enrollment. No HCC cases were
69 identified as part of routine HCC surveillance but were evaluated due to clinical symptoms.

70 Survival follow-up: Contact information of both the patient and of secondary contacts was
71 obtained at enrollment and used for participant tracing, primarily by telephone, to ascertain vital
72 status at 1, 3, 6 and 12 months after study enrolment. For individuals that were not reachable
73 following three attempted telephone contacts, field tracing was carried out using address
74 information. Using these follow-up procedures, vital status was verifiable for >95% of HCC

75 cases, resulting in 419 HCC cases analyzable at three months or beyond for survival outcomes.
76 Additional information obtained included whether the patient was hospitalized or not, date of
77 death and reported cause of death obtained from death certificates if available to informant. Vital
78 status and cause of death information was also determined by reviewing hospital records for
79 those who were hospitalized.

80 Statistical analysis: Pearson chi-squared (χ^2) and Wilcoxon rank-sum (Mann-Whitney) tests
81 were used to compare baseline categorical and continuous variables (e.g., demographics,
82 symptoms, signs), respectively, stratified by HIV status. The primary outcome measure in this
83 analysis was mortality risk following HCC diagnosis (study enrolment was used as a proxy).
84 Kaplan-Meier methods were used to compare survival curves by key factors of HIV status and
85 HIV-associated markers. Cox-proportional hazards regression was used to estimate the crude
86 and adjusted hazard ratios (HR) and corresponding 95% confidence intervals (95% CI) for
87 mortality risk. The multivariable model assessed the association between HIV status and
88 mortality risk controlling for potential confounders defined *a priori* including age, sex, education,
89 history of alcohol use, history of cigarette smoking, HBsAg, anti-HCV, and urine *Schistosomiasis*
90 CCA. All *p*-values were based on a two-sided hypothesis test with a type-1 error ($\alpha = 0.05$).
91 Stata 13.0 (College Station, TX) was used for statistical analysis.

92

93 **Results**

94 Characteristics of 441 HCC cases are shown in Table 1, overall and stratified by HIV
95 status (N= 79, 18.0% were HIV-infected). Two-thirds of HCC cases were male, and the median
96 age was 42 years (inter-quartile range, [IQR] 31-55 years). Almost half reported a history of
97 alcohol intake, while 82 (19.0%) reported history of cigarette smoking. Co-infections were
98 common: 192 (43.9%) were HBsAg positive, 30 (6.9%) were anti-HCV positive, and 214
99 (52.8%) were urine CCA positive for active *Schistosomiasis* infection. Overall, 219 (50.3%) of

100 cases had elevated AFP concentrations ≥ 100 IU/ml), while 344 (78.2%) had serum AST levels
101 above 45 U/l, 244 (55.4%) had serum ALT levels above 40 U/l, and INR was raised above the
102 upper limit of normal (1.15) among 351 (82.2%) of cases, and three-quarters of cases had
103 multifocal disease by ultrasound.

104 HIV-associated HCC cases were a median of three years older (45 vs. 42 years, $P=$
105 0.62) although their age range was notably more restricted with almost two-thirds between 31-
106 50 years of age compared to non-HIV HCC cases with an equal proportion in the extremes of
107 age ($P= 0.001$). HIV-associated HCC cases were less educated, reported more prior alcohol
108 use and cigarette smoking, and had higher AST levels at diagnosis. Among the HIV-associated
109 cases, 69 (87.3%) had been diagnosed with HIV prior to study enrollment. The median (IQR)
110 CD4 count was 308 (5-1244) cells/ml³ among all HIV-associated cases, 316 (25-1244) among
111 those with known HIV infection prior to HCC diagnosis, and was 262 (5-1005) among those not
112 receiving cART. Of the 69 cases with known HIV infection, 58 (84.1%) were on some form of
113 cART and 32 (58.2%) of these reported consistent use of cART in the month prior to study
114 enrolment. Overall, 51 (64.6%) had an HIV viral load less than 200 copies /ml while among
115 those receiving ART 45 (77.6%) were virally suppressed at this cutoff.

116 **Clinical presentation**

117 At enrollment, most HCC cases reported multiple symptoms (Figure 1, Panel A). Pain
118 (95%) and weight loss (93%) were almost uniformly reported, followed by abdominal fullness
119 and anorexia in over 80% of participants. As shown in Figure 1, the frequency and patterns of
120 reported symptoms at study enrollment were similar for both HIV-infected and HIV-uninfected
121 cases, although more reports of nausea were reported by the HIV-uninfected cases ($p=0.05$).
122 Similarly, in terms of clinical signs noted on standardized clinical examination, HIV-associated
123 HCC cases were similar to non-HIV HCC except that flapping was exhibited more frequently
124 among the HIV-infected cases ($p=0.004$), (Figure 1, Panel B).

125 **Survival among HCC cases**

126 Through 12 months follow-up post-HCC diagnosis with an accumulated 1,209 person-
127 months at risk, vital status was verifiable for all but 22 (5.0%) HCC cases; 4 (5.0%) of which
128 were HIV-infected. There were no significant differences between the participants whose vital
129 status was ascertained at 12 months post HCC diagnosis versus those who were lost to follow-
130 up regarding the distribution of baseline characteristics.

131 Kaplan-Meier risk curves overall and by HIV status and severity of immunosuppression
132 at diagnosis are depicted in Figure 2. The overall median observed survival time was only 42
133 days (IQR, 20, 106) after HCC diagnosis. In comparison of HIV-associated HCC to non-HIV
134 HCC, the median survival was 29 days (IQR, 16, 85) and 45 days (IQR, 20, 112), respectively.
135 Overall, cumulative risk of death by 1, 3, 6 and 12 months was 42.6%, 72.7%, 84.7% and
136 90.7%, respectively; which was higher in the HIV versus non-HIV groups at earlier timepoints:
137 54.4% vs. 44.6% at 1 month (P 0.13), 75.9% vs. 70.1% at 3 months (P 0.47), and 84.8% vs.
138 81.7% at 6 months (P 0.77), respectively.

139 The crude hazard ratio (HR) and corresponding 95% confidence intervals (CI) of death
140 after HCC diagnosis associated with HIV infection was 1.20 (0.93-1.56), $p=0.16$. In
141 multivariable analysis adjusting for age, sex, education, alcohol and smoking history, HBsAg,
142 anti-HCV and urine schistosomiasis CCA, HIV infection was associated with increased mortality
143 risk although this difference did not achieve statistical significance, aHR (95% C) = 1.30 (0.97-
144 1.74), $p=0.081$. Compared with HIV-uninfected counterparts, the higher mortality risk observed
145 among HIV-infected individuals was significant among those with more severe HIV-disease
146 (less than 200 CD4 cells per cubic milliliter), aHR (95% C) = 2.12 (1.23-3.53), $p=0.004$, but not
147 among individuals with 200 or more CD4 cells per cubic milliliter, aHR (95% C) = 1.15 (0.82-
148 1.60), $p=0.417$. In a similar trend of increased mortality risk associated with more advanced HIV
149 disease albeit not statistically significant, compared to non-HIV HCC cases, higher mortality risk

150 was observed among PLWH with detectable HIV viremia [aHR (95% C) = 1.47 (0.94-2.30) with
151 VL \geq 200 copies/ml", p=0.095] than observed among those with current viral suppression [aHR
152 (95% C) = 1.23 (0.87-1.73), p=0.243].

153

154 **Discussion**

155 This investigation reveals the exceptionally high mortality associated with the diagnosis of
156 HCC in sub-Saharan Africa. While there were no major differences detected in how HCC
157 presented in PLWH, mortality was exceptionally fast in those with advanced HIV. Collectively,
158 these data contribute to the urgency to identify and deploy new methods to prevent, detect and
159 cure HCC worldwide.

160 HCC in sub-Saharan Africa, and particularly in Uganda, is one of the most common
161 causes of cancer and of cancer-attributable death. Previously, we leveraged Kampala Cancer
162 Registry data to identify an increasing trend in HCC incidence rates in Uganda which predated
163 widespread availability of cART.²⁰ Our suspicion, similar to what has been observed in more
164 developed settings, is that HCC incidence rates are likely to continue to increase as PLWH
165 survive into older ages in a setting with substantive chronic HBV infection and aflatoxin
166 exposure. While this study does not calculate population-level HCC incidence rates, we do note
167 that almost one in five HCC cases were HIV-infected, which is among the highest HIV
168 prevalence reported of any prior non-targeted HCC study²¹⁻²³.

169 Survival in patients with untreated advanced HCC is poor, although varying 1-year
170 survival rates and prognostic factors have been reported depending on demographic and clinical
171 characteristics, different timing of referral and diagnostic criteria, underlying cause of liver
172 disease, severity of the underlying cirrhosis, and tumor burden.²⁴⁻²⁶ The short median survival
173 after HCC diagnosis observed in this study is consistent with an Uganda study from three
174 decades ago which characterized similar survival among untreated HCC patients¹⁵. Studies
175 looking at survival in which participants received treatment for HCC disease have reported a

176 relatively longer median survival beyond 10 months.²⁶⁻²⁸ Unfortunately, a recent review from
177 sub-Saharan Africa indicates that only 3% of 1315 HCC cases from sub-Saharan Africa
178 underwent any HCC specific therapy.²⁹ Today, HCC in Africa represents an advance diagnosis
179 with minimal treatment options with limited advancement over decades.

180 Despite the limited survival time, we observed an HIV effect towards more rapid
181 mortality. This effect was generally observed by HIV status, but was accentuated when
182 evaluating markers of more advanced HIV disease, notably CD4 count less than 200 cells/ml.
183 Theoretically, PLWH engaged in a well-developed, HIV care delivery system in Uganda and
184 achieving viral suppression should potentially be more readily identified at earlier HCC stages.
185 Our data do not support this hypothesis however. Almost 80% of HCC cases in our study had
186 multifocal liver lesions at diagnosis, irrespective of HIV status. The clinical signs, symptoms and
187 laboratory studies of HCC cases also were very similar by HIV status. Despite this, PLWH with
188 more advanced immunosuppression had to 30% more rapid time to death. We are unable to
189 establish the underlying mechanism for advanced HIV disease resulting in earlier mortality, and
190 advanced liver cirrhosis itself may contribute to changes in CD4 counts ³⁰.

191 To our knowledge, this is the first African study to report the impact of HIV infection on
192 survival after HCC diagnosis. Data from other regions are mixed; a study by Yopp et al from a
193 single European institution reported that HIV infection was not associated with HCC survival.³¹
194 In contrast, other European studies^{32,33} showed a worse survival outcome among HIV-infected
195 HCC patients; these studies were relatively small retrospective studies from tertiary care
196 academic centers with possible biases of patient selection and treatment options. Despite
197 several analyses of large-scale HIV and cancer datasets from the US that excluded HCC,³⁴
198 inferences from national data did find that PLWH with HCC presented at more advanced stages
199 and had worse survival compared to non-HIV HCC even after accounting for a variety of health
200 associated factors. In what purports to be among the largest international studies of the HIV
201 effect on HCC survival (N=132 HIV associated HCC cases) from four continents (excluding sub-

202 Saharan Africa), the authors estimated around the 25% increased mortality risk associated with
203 HIV, despite appropriate ART and viral suppression.³⁵

204 For 15% of HIV-associated HCC cases, the diagnosis of HCC prompted the initial
205 identification of HIV infection. The small proportion of HCC cases who were unaware of their
206 HIV status prior to study enrolment is consistent with data that has shown that Uganda has high
207 rates of HIV testing and treatment.^{36,37} Around 77% of HIV-infected cases on cART had
208 undetectable HIV viral loads which is similar to findings by Byonabye et al³⁸ that have shown
209 that PLWH in Uganda in care achieve high levels of viral suppression. Notably, these higher
210 levels of viral suppression occurred despite only 57% of persons with advanced HCC disease
211 reporting optimal ART adherence, emphasizing the potency of current ART regimens despite
212 less-than-perfect adherence.

213 This study had both strengths and limitations. Many prior investigations of HCC in sub-
214 Saharan Africa have been limited by the relatively small size and the reliance on convenience
215 sampling or compilation of sporadic cases without standardized assessment of symptoms,
216 clinical and laboratory findings or ultrasonographic features. Leveraging our standardized data
217 collection procedures, we report uniformly-collected interview, clinical, laboratory, and
218 ultrasonographic data among a large number of highly-characterized HCC cases systematically
219 enrolled in a hospital-based study in Kampala, Uganda. The study was large with complete
220 registration of participants, and though it was hospital-based, it was within a referral hospital
221 with patients coming from several regions around the country with limited options for diagnosis
222 and treatment for HCC. Despite the relatively large size for an HCC study from Africa, the
223 numbers of cases were limited when evaluating stratified analyses by CD4 count or viral
224 suppression status. Only a few of the patients with suspected HCC had a confirmatory
225 histopathologic diagnosis and the possibility that other cancers such as cholangio-carcinoma or
226 unspecified types being diagnosed as HCC is plausible. We limited misclassification of liver
227 metastases as HCC by noting the differing ultrasonographic patterns and use of AFP, generally

228 not elevated with metastases. Further , HCC accounts for approximately 70-90% of primary liver
229 cancers^{20,39,40} in Uganda and in sub-Saharan Africa .

230 Although HCC cases with earlier stage symptoms can be identified, it remains unclear if
231 more aggressive diagnostic approaches can identify earlier-stage HCC and improve survival. It
232 is also important to start surveillance for HCC in high-risk patients including those with HIV
233 infection in endemic sub-Saharan countries to ensure early diagnosis and thereafter linkage to
234 localized curative treatments in order to modify the statistics caused by this lethal disease.

235 **Conclusions**

236 Prognosis for HCC in sub-Saharan Africa is dismal and has largely remained the same
237 over the last few decades^{15,41} Similar to the nihilism confronting HIV care delivery in sub-
238 Saharan Africa prior to the widespread scale up of ART programs, substantial skepticism exists
239 on whether HCC can be identified in earlier stages and curative treatments be provided to
240 impact this current situation. However, global efforts have identified viral hepatitis elimination as
241 a primary goal and increasingly, locally curative therapies and tumor resection (without
242 transplantation) for earlier stage disease may become increasingly available. Within the past
243 two years, the first liver resections for HCC have been performed in Uganda.

244 Advanced HIV disease appears to accelerate mortality among HCC patients with this
245 already highly lethal disease. However, the existing HIV care infrastructure in sub-Saharan
246 Africa where patients are engaged over long periods of time, advanced diagnostic testing is
247 available, and antivirals can be successfully delivered provides a framework on which to
248 leverage HCC surveillance programs. Leveraging this human and infrastructure capacity,
249 resources should be invested to develop and evaluate the integration of active HCC surveillance
250 programs within HIV care delivery systems, targeting both PLWH and high-risk, HIV uninfected
251 persons, to identify patients with limited HCC amenable to locally available curative therapies.

252

253 **Declarations**

254 *Ethics approval and consent to participate*

255 This study was approved by the Institutional Review Boards of Makerere University School of
256 Medicine and Johns Hopkins University. Written informed consent was obtained from all
257 patients before participation in the study.

258 *Availability of data and materials*

259 The datasets used and/or analysed during the current study are available from the
260 corresponding author on reasonable request.

261 *Competing interests*

262 None of the authors has financial, consultant, institutional or other relationships that might lead
263 to a bias or conflict of interest.

264 *Authors' contributions*

265 SN conceived the presented research idea and took the lead in writing the draft manuscript. AJ
266 contributed to creating the final study dataset, reconstruction of study variables and took the
267 lead in data analysis. GK, AJ and PO provided overall supervision and guidance of statistical
268 analysis and contributed to revisions of the manuscript. GK,PO and DT conceptualized the
269 study on which this manuscript is based, were the lead investigators and contributed to revisions
270 of the manuscript.. All authors have read and approved the final manuscript.

271 *Acknowledgements*

272 We thank the study participants and their caregiving families who agreed to participate in this
273 study, and the study teams in Kampala and Gulu who have shown great dedication and
274 resilience over the years. We wish to acknowledge the support from the Infectious Diseases
275 Institute in Kampala, Uganda Cancer Institute, Mulago National Referral Hospital and St. Mary's
276 Hospital, Lacor, Uganda.

277 We would also like to thank Drs. Julie Nabweteme, Eve-Marie Benson and Fred Okuku for their
278 contribution to this study.

279 *Funding statement*

280 This work was supported by grant U54-CA190165 from the National Cancer Institute. GDK was
281 supported by grant K24-AI118591 from the National Institute of Allergy and Infectious Diseases.

282 The funders had no role in study design, data collection and analysis, decision to publish or
283 preparation of the manuscript.

Table 1: Characteristics of HCC cases at diagnosis, stratified by HIV status

Characteristics	Overall* N=441	HIV positive n=79 (18.0%)	HIV negative n=361 (82.0%)	p-value
Socio-Demographic				
Age (years), median (IQR)	42 (31-55)	45 (37-52)	42(30-56)	0.463 ^a
Age groups, n (%)				
30 years or younger	104 (23.6)	9 (11.4)	95 (26.3)	0.001^b
31-50 years	187 (42.5)	48 (60.8)	139 (39.0)	
Above 50 years	149 (33.9)	22 (27.9)	127 (35.2)	
Males, n (%)	295 (67.1)	51 (64.6)	244 (67.6)	0.600 ^b
Education attained				
Primary or less	233 (53.0)	52 (65.8)	181 (50.1)	0.034^b
Secondary	139 (31.6)	20 (25.3)	119 (33.0)	
Tertiary	68 (15.4)	7 (8.9)	61 (16.9)	
Alcohol consumption, n (%)	194 (44.1)	48 (60.8)	146 (40.4)	0.001^b
Cigarette smoking, n (%)	82 (19.0)	22 (28.0)	60 (17.0)	0.025^b
Clinical				
Physical activity, Karnofsky score, < 50, n (%)	44 (10.1)	10 (12.7)	34(9.5)	0.39 ^b
Hand grip strength, > 45 pounds, n (%)	188 (47.0)	31 (41.3)	157 (48.2)	0.310 ^b
Laboratory				
HBsAg positive, n (%)	192 (43.9)	35 (44.9)	157 (43.6)	0.900 ^b
Anti-HCV positive, n (%)	30 (6.9)	2 (2.5)	28 (7.8)	0.137 ^b
Active <i>Schistosomiasis</i> (Urine CCA) positive, n (%)	214 (52.8)	37 (50.0)	177 (53.5)	0.610 ^b

AST (U/l), >45, n (%)	344 (78.2)	69 (87.3)	275 (76.2)	0.035^b
ALT (U/l), >40, n (%)	244 (55.5)	48 (60.8)	196 (54.3)	0.319 ^b
INR >1.15, n (%)	351 (82.2)	66 (86.8)	285 (81.2)	0.321 ^b
AFP (IU/mL), ≥100, n (%)	218 (50.2)	39 (50.0)	179 (50.3)	1.000 ^b
AFP (IU/mL), ≥400, n (%)	199 (45.9)	33 (42.3)	166 (46.6)	0.532 ^b
HIV load (copies/ml) ^c				
<200	--	51 (64.6%)	--	
≥200	--	28 (35.4%)	--	
CD4 cell count (cells/mm3) ^d				
<200	--	21 (26.6%)	--	
≥200	--	58 (73.4%)	--	
Ultrasound imaging				
Multifocal disease, n (%)	316 (73.6%)	61 (77.2%)	255 (72.9%)	0.730 ^b

Key: AFP, alpha-fetoprotein; ALT, alanine aminotransferase; anti-HCV, hepatitis C virus antibody; AST, aspartate aminotransferase; CCA, circulating cathodic antigen, a urine-based, point-of-care test for active *Schistosomiasis* diagnosis; HBsAg, hepatitis B surface antigen; INR, international normalized ratio, a measure of how long it takes blood to form a clot; IQR, interquartile range; ^a p-value from Wilcoxon rank-sum test; ^b p-value from Fisher's exact test. Highlighted p-values are statistically significant. ^c HIV viral suppression defined as less than 200 copies of HIV per millilitre of blood. ^d HIV severe disease defined as less than 200 CD4 cells per cubic millilitre). *Missing data: AFP (n=6); anti-HCV (n=2); AST (n=1); grip strength (n=39 (8.8%)); HBsAg (n=2); HIV (n=1); INR (n=13); Multifocal disease (n=11)

Figure 1: Symptoms (A) and signs (B) of liver diseases at hepatocellular carcinoma diagnosis stratified by HIV infection status

All rights reserved. No reuse allowed without permission.
Figure 1 A - Symptoms reported by patients at HCC diagnosis, stratified by HIV infection.

Figure 1 B- Clinical signs exhibited by patients on examination at time of diagnosis; stratified by HIV infection. Patients were examined for clinical signs of liver disease and HCC.

Figure 2: Survival after hepatocellular carcinoma diagnosis, overall, by HIV status, and by HIV and CD4 cell category

Figure 2 shows Kaplan-Meier curves depicting probability of death within 12 months after HCC diagnosis, (A) overall, (B) by HIV-infection status ($p=0.21$), (C) by HIV-infection status and CD4 cell categories (HIV-uninfected versus HIV-infected with ≥ 200 CD4 cells/ml versus HIV-infected with < 200 CD4 cells/ml ($p=0.05$), and comparison of HIV-infected group with < 200 CD4 cells/ml versus others (HIV-infected with ≥ 200 CD4 cells/ml or HIV-uninfected), ($p=0.02$). ^a p-value from non-parametric Log-rank test, a global test to compare if the survival between two or three independent groups, B and C respectively, are identical (overlapping) or not.
