47 **Abstract**

48 Relapsing-remitting multiple sclerosis is the most common type of multiple sclerosis
49 characterized by periods of relapses and generating various motor symptoms. These symptoms are
50 associated with the corticospinal tract integrity, which is quantified by means of corticospinal
51 plasticity which can be probed via transcranial magnetic stimulation and assessed with motor
52 threshold, motor evoked potential and central motor conduction time. Several factors, such as
53 exercise and interlimb coordination, can influence corticospinal plasticity. Previous work in
54 healthy and in stroke patients showed that the greatest improvement in corticospinal plasticity
55 occurred during in-phase bilateral arm exercises. Altered corticospinal plasticity due to bilateral
56 cortical lesions is common in multiple sclerosis, yet, the impact of these type of exercises in this
57 cohort is unclear. The aim of this concurrent multiple baseline design study is to investigate the
58 effects of in-phase bilateral exercises on corticospinal plasticity and on clinical measures using
59 transcranial magnetic stimulation and standardized clinical assessment, in five people with
60 relapsing-remitting multiple sclerosis. The intervention protocol will last for 12 consecutive weeks
61 (30-60 minutes /session x 3 sessions/week) and include in-phase bilateral movements of the upper
62 limbs, adapted to different sports activities and to functional training. To define functional relation
63 between the intervention and the results on corticospinal plasticity (i.e., resting motor threshold,
64 motor evoked potential amplitude, latency) and on clinical measures (i.e., balance, gait, bilateral
65 hand dexterity and strength, cognitive function), we will perform a visual analysis followed by
66 multilevel modelling and the single case educational design-specific mean difference in order to
67 estimate the magnitude of the effect size across cases. We assume that possible effects from our
68 study, will introduce a type of exercise that will be effective during the disease progression.

69 **Introduction**

70 Multiple sclerosis (MS) is the most common inflammatory demyelinating and
71 neurodegenerative disease of the central nervous system (1). The global prevalence of MS during
72 the last decade has increased by 30%, while the number of people suffering with MS worldwide
73 is estimated at approximately 2.8 million(8). The low mean age of diagnosis (i.e., 32 years old),
74 along with an average of seven years' shorter life expectancy (i.e., 74.7 years) compared to the
75 general population (4–6), highlights the need for a lengthy support, resulting in increased financial
76 burden (7). The direct cost from health care services and the indirect cost due to productivity loss
77 because of physical inactivity of people with MS, indicates a huge financial burden on families,
78 healthcare systems, and societies in general. Recent studies reported that the annual mean cost of
79 health care systems for people with MS living in Europe is about €40,000 (8). Additionally, both
80 MS patients and their caregivers, who usually are family members, are facing several
81 psychological and social difficulties due to social isolation, poorer quality of life, reduced
82 productivity and lower general health levels (9,10).

83 Relapsing-remitting multiple sclerosis (RRMS), is the most common type of MS and is
84 characterised by periods of relapses followed by partial or complete recovery (11). Inflammatory
85 lesions are commonly found bilaterally in both white and grey matter of the central nervous system
86 (12,13), resulting in diverse clinical condition and symptoms, that include motor and cognitive
87 impairments, vision deficits, depression and fatigue (13–15). Those symptoms results in
88 significantly low quality of life (16,17), which subsequently causes the need for a lifelong support
89 and management of symptoms for most people with RRMS (18).

90 Motor symptoms in RRMS are associated with changes in corticospinal tract integrity and
91 neuroplasticity (19–25). The corticospinal tract is one of the major motor descending pathways

92 providing voluntary motor function in humans (26). The neuroplasticity of the corticospinal tract,
93 as defined by changes in neuron structure or function detected either directly from measures of
94 individual neurons or inferred from measures taken across populations of neurons (27), is an
95 essential factor that predicts clinical recovery in the post-relapse stage of people with RRMS
96 (28,29). Corticospinal plasticity can be probed using Transcranial Magnetic Stimulation (TMS)
97 (30,31) and characterized via certain TMS-specific neurophysiological measures including resting
98 motor threshold, motor-evoked potential (MEP) amplitudes and the central motor conduction time
99 (31). Motor threshold and MEP are the hallmark measures of corticospinal excitability in MS (32),
100 whereas the central motor conduction time expresses the time taken for neural impulses to travel
101 over the central nervous system on their way to the target muscle (33).

102 Corticospinal plasticity is exercise-dependent (34,35) and influenced by various factors
103 (36,37), such as aerobic exercise (22,38–40), resistance training (22,40), as well as interlimb
104 coordination (41,42). Previous studies that assessed corticospinal plasticity using TMS in healthy
105 participants and in chronic stroke survivors, reported that interlimb coordination and especially in-
106 phase bilateral movement has the strongest effect on corticospinal plasticity (43–46). These effects
107 are thought to be due to the suppression of cortical inhibition (46,47) and the simultaneous
108 activation of homologous representations of the motor cortices, which involves interhemispheric
109 facilitation via transcallosal connection between the primary motor cortex and the supplementary
110 motor area (48,49).

111 Despite the broad literature on the effects of different types of exercises on the
112 neuroplasticity in people with RRMS (39,50–52), it is unclear whether in-phase bilateral exercises
113 can promote motor related neuroplastic changes in RRMS. In light of evidence that people with
114 RRMS have bilateral cortical lesions (53) which cause bilateral changes of corticospinal tract

115 integrity (23,25), these findings raise the question about the effects of in-phase bilateral exercises
116 on corticospinal plasticity. Such effects would provide strong evidence about whether exercise, in
117 particular in-phase bilateral exercise, can influence the corticospinal plasticity in RRMS.

118 The aim of this study is to investigate whether a 12-week intervention protocol of in-phase
119 bilateral exercises (independent variable) for the upper limbs, which are adapted to sports activities
120 and to functional training, can significantly affect the corticospinal plasticity and subsequently the
121 individual clinical condition of people with RRMS. Our primary hypothesis is that a significant
122 improvement of corticospinal plasticity will be detected bilaterally, caused by the specific
123 intervention protocol which includes in-phase bilateral exercises of the upper limbs in people with
124 RRMS. We will assess the corticospinal plasticity bilaterally using TMS and calculate TMS-
125 specific measures (45). Visual analysis will be conducted separately for each variable and results
126 will be presented graphically according to the level, trend, and stability, to define functional
127 relationships between the intervention protocol and the corticospinal plasticity. Also, quantitative
128 analysis within cases will be conducted using Cohen's d, Hedges' g and piecewise regression
129 analysis, as well as quantitative analysis will be performed between cases, using a multilevel
130 modelling. To estimate the overall effect size, we will use the single case educational design, and
131 the mean difference index (54).

132 Exploratory analyses in Stage 2 will investigate the effects of the specific exercises protocol
133 on clinical symptoms using clinical assessment (i.e., gait, balance, strength, hand dexterity,
134 cognitive function) and the Modified Fatigue Impact Scale (55). Visual and quantitative analysis
135 will be conducted as described above.

136 The study follows a concurrent multiple baseline design across subjects (56), which
137 involves five people with RRMS. The specific design has the advantage to verify the cause-effect

138 inference clearly by the staggered duration through separate baseline phases (57). Consequently,
139 we assume that possible effects from our study will promote a novel approach in the field of
140 neurorehabilitation and will introduce a type of exercise that will be effective during the disease
141 progression.

142

143 **Materials and Methods**

144

145 **Participants**

146 All participants will be recruited from August to October 2022 and evaluated by an
147 experienced neurologist at The Cyprus Institute of Neurology and Genetics. The inclusion criteria
148 include 1) diagnosed with RRMS, 2) Expanded Disability Status Scale score between three and
149 five (58), 3) aged between 30 and 70 years, 4) no relapse within 30 days and 5) Mini Mental State
150 of Examination score between 24 and 30 (no cognitive impairment) (59). The exclusion criteria
151 include 1) metal implants, 2) history of any disease affecting the central nervous system other than
152 MS, 3) history of cardiovascular disease, 4) mental disorders, and 5) severe orthopaedic disorders,
153 6) pregnancy, 7) visual deficit, 8) hearing impairments, 9) epileptic seizures and 10) spasticity
154 level on upper or lower limbs more than 1+ (slight increase in muscle tone) according to Modified
155 Ashworth Scale (60). Additionally, participants will be advised to continue their usual prescribed
156 medication throughout the study duration, and they will be advised to continue their usual routine
157 avoiding receiving any other exercise program during this study. Furthermore, all participants will
158 read and sign a written informed consent while all procedures are approved and conducted in

159 accordance with the ethical guidelines of the Cyprus National Bioethics Committee before
160 recruitment.

161 **Study design**

162 The study follows a concurrent multiple baseline design across subjects, without blinding
163 and has been designed according to the ‘What Works Clearinghouse’ criteria for single case studies
164 (56). According to Kratochwill et al. (56), three participants, with collection of three data points
165 across different phases is the minimum number needed to meet the standard criteria, while four or
166 more is recognized as more reliable. We aim to include five participants to ensure the reliability
167 of the results in case of dropouts, as well as to record several data points across the baseline phase,
168 five data points during the intervention phase and three data points in the follow up phase. During
169 the experimental procedure, all participants will begin the study with the baseline phase at the
170 same time while the intervention phase is introduced staggered across patients and time (Fig 1).
171 The intervention will be introduced systematically in one patient while baseline data collection
172 continues in the others without any intervention. The cause-effect inference can be clearly verified
173 by the staggered duration through separate baseline phases (57). Subsequently, if the intervention
174 (i.e., in-phase bilateral exercises) is the sole cause of improvement in participants’ conditions, the
175 proposed outcome measures will not change for the participants that remain in the baseline phase
176 but will be improved only for those in the intervention phase.

177
178 **Figure 1. Timeline and schematic representation of the study’s design.** Grey colour represents
179 the intervention phase. Each row (A-E) represents a different participant. (c) clinical assessment.
180 (n) neurophysiological assessment via TMS. (f) Modified Fatigue Impact Scale questionnaire.

181 Every cell represents a different week, so every procedure which is included (i.e., c, n, f) will be
182 performed during the corresponding week but in different days.

183

184 **Baseline**

185 As depicted in Figure 1, all patients will begin the baseline phase simultaneously. Each
186 patient will undergo a baseline phase of a different time duration, starting with three weeks for the
187 first participant and gradually increasing by one week for each participant. During the baseline
188 phase, each participant will be assessed on the Modified Fatigue Impact Scale (55) on the first
189 week. The neurophysiological (primary outcome measures) and clinical (secondary outcome
190 measures) assessments will be repeated each baseline week for all participants.

191 **Intervention**

192 Immediately after the end of each baseline phase, the intervention phase will begin
193 staggered across participants and time accordingly (Fig 1). The intervention protocol consists of
194 exercises based on in-phase bilateral movements of the upper limbs, which are adapted to different
195 sport activities and to fitness functional exercises, organized in a circuit training considering the
196 MS exercise recommendations (61). Since no established protocols have been previously reported,
197 for the needs of our study a certified fitness instructor will design these protocols adapted to
198 different sport activities. Specifically, each session will consist of one to three sets, consisting of
199 10–15 repetitions of 9 different exercises targeting large muscle groups of the upper limbs
200 (shoulder flexors, extensors, rotators, abductors and adductors, elbow flexors and extensors, hand
201 and finger flexors and extensors). Additionally, three exercises will target large lower limb muscle
202 groups (hip flexors, extensors, abductors and adductors, knee and ankle flexors and extensors) to
203 be performed in between the upper limbs exercises to allow relaxation of the upper limb muscles.

204 The specific exercises will include sports activities of basic technical skills of basketball
205 (e.g., different types of passing, catching and throwing the ball) and volleyball (e.g., different types
206 of passing and receiving the ball), whereas the fitness exercises will include shoulder rows,
207 shoulder lateral raises, elbow flexions, elbow extensions, as well as using the diagonal movements
208 form proprioceptive neuromuscular facilitation technique (62) by the use of resistance elastic
209 bands (51), as well as exercises with the patients' own body weight (e.g., pushups, TRX) (63). To
210 maintain the interest of the participants, the exercise program will be modified throughout the
211 course of the 12-week intervention period via changing the level of difficulty. For example, elastic
212 bands with different resistance levels will be used, the number of repetitions and sets will vary
213 along with the specific exercise and body position (e.g., from sitting to standing).

214 The intervention phase for each participant will consist of 12 consecutive weeks in which
215 the proposed protocol will be performed three times per week, for 30-60 minutes each session,
216 adapted to each participant's fatigue and fitness level. Each participant has to complete at least 27
217 (75%) out of 36 sessions in order to be included in the data analysis (51). Every intervention
218 session will consist of a five minutes' warm-up (i.e., whole body range of motion exercises),
219 followed by the main sport activities and fitness exercise protocol as described above, and a cool
220 down session for five minutes (i.e., passive stretching exercises of the muscle groups which are
221 involved in the main part).

222 Additionally, starting from the third intervention week, we will perform five
223 neurophysiological (see primary outcome measures) and five clinical assessments (see secondary
224 outcome measures) (i.e., once a week), to collect five data points for every participant across the
225 intervention phase. Moreover, each participant will also be asked to complete once the Modified
226 Fatigue Impact Scale (see secondary measures) at the end of the intervention phase (51) (Fig 1).

227 **Follow-Up**

228 As depicted in Figure 1, every participant will undergo three follow-up assessments in total,
229 after finishing the training protocol lasting from February to May 2022, so to explore possible
230 long-lasting effects. Each follow-up assessment includes both neurophysiological and clinical
231 measures (including Modified Impact Scale). We will perform the first follow-up assessment at
232 the end of the fourth post-intervention week, the second one at the end of the eighth post-
233 intervention week and we will perform the last follow-up assessment at the end of the 12th post-
234 intervention week (Fig 1).

235 **Data Acquisition of Outcome Measures**

236 **Primary Outcome Measures**

237 We will assess the corticospinal plasticity using single pulse TMS in the neurophysiology
238 lab of the Cyprus Institute of Neurology and Genetics. Using electromyography (EMG) signals,
239 we will analyse bilateral cortical excitability and bilateral central motor conduction time to
240 determine corticospinal plasticity and therefore to test the primary hypothesis. The resting motor
241 threshold and the MEP amplitude of Abductor Pollicis Brevis muscle will define cortical
242 excitability, while we will use the MEP latency to calculate the central motor conduction time (see
243 below). During all neurophysiological assessments, participants will be in a relaxed sitting position
244 in a comfortable chair with feet touching the floor and both arms will be placed on cushioned
245 armrests and with the head rested on a cushion. To ensure methodological consistency, we will
246 collect all data by performing the same methodological procedures for both conditions (i.e.,
247 cortical excitability and central motor conduction time) bilaterally (one side per assessment),
248 across participants and across all time points.

249

250 **EMG recording**

251 During both TMS and peripheral stimulation, surface EMG of the Abductor Pollicis Brevis
252 muscle will be collected. We will follow a standard skin preparation (64) and surface disk
253 electrodes placement procedures by attaching the electrodes over the end plate region of the
254 Abductor Pollicis Brevis muscle (65). Specifically, the anode (red colour) electrode will be placed
255 distally, whereas the cathode (black colour) electrode proximally. A ground reference electrode
256 will be attached on the lateral condyle of the elbow, of the corresponding upper limb. Additionally,
257 all signals will be filtered with the help of the KeyPoint Net Software Electromyography using a
258 bandwidth of 2 Hz–10 kHz, 1mV/D for the MEP sensitivity with a single-pulse stimulation
259 frequency.

260 **Peripheral stimulation**

261 In addition to MEP latency, calculating the central motor conduction time requires two
262 peripheral derived measures, the F wave (i.e., late muscle response) and the M wave (i.e., direct
263 muscle response) (66,67). Therefore, we will initially deliver peripheral stimulation on the median
264 nerve at the wrist, approximately in 8 cm distance from the cathode electrode (65), while collecting
265 EMG from the Abductor Pollicis Brevis muscle (68) of the corresponding upper limb. In order to
266 determine possible changes in central motor conduction time, we will analyse F and M wave (69).

267 **TMS assessment**

268 Following TMS recommended guidelines concerning safety and experimental conditions
269 (70,71), we will assess bilateral cortical excitability and bilateral central motor conduction time.
270 We will apply TMS single pulses (72) via figure-eight coil (C-B60; inner diameter: 35mm, outer
271 diameter: 75mm), connected to the MagPro R20 (MagVenture User Guide, United Kingdom
272 edition, MagVenture A/S, Denmark). The coil will be oriented tangentially over the contralateral

273 motor area of the brain, relative to the target muscle (i.e., Abductor Pollicis Brevis), with a
274 posterolateral handle pointing in approximately 45 degrees angle to the sagittal plane, as a result
275 to induce current in a posterior-anterior direction in the brain (73).

276 For the TMS procedures, we will first find the optimal stimulation site (i.e., hot-spot), next
277 we will determine the resting motor threshold, and then apply a bout of single pulses using
278 suprathreshold stimulation. To determine hot-spot (i.e., the spot in which the largest response of
279 the target muscle is elicited), we will deliver single pulses at low intensities (e.g., ~20% maximum
280 stimulator output) and gradually increase it by 5%, maximum stimulator output until we will reach
281 the intensity that will elicit three consecutive MEPs with peak-to-peak amplitude greater than
282 50mV (74,75). Then, we will mark the position of the coil on the skull with a water-resistant ink,
283 so to determine the resting motor threshold of the target muscle. Resting motor threshold is the
284 minimum stimulation intensity needed to produce MEPs of the target muscle, which is defined by
285 the hot-spot. To identify the resting motor threshold of the Abductor Pollicis Brevis muscle, we
286 will employ an adaptive threshold-hunting method, the Motor Threshold Assessment Tool (MTAT
287 2.0) (76) (available at <http://clinicalresearcher.org/software.htm>). The specific method has the
288 advantage of speed without losing accuracy when compared to the relative-frequency methods
289 based on the Rossini–Rothwell, although both methods have similar precision (77). Then, to
290 quantify the MEP-derived measures of interest (i.e., MEP amplitude, latency), we will apply 25
291 suprathreshold stimuli (78) at 120% of the resting motor threshold (79).

292

293 **Secondary Outcome Measures**

294 The secondary outcome measures will include all the clinical assessments, which will be
295 performed in the physiotherapy unit of the Cyprus Institute of Neurology and Genetics. An

296 experienced physiotherapist will perform all clinical assessment with exact the same
297 methodological procedures.

298 **1. Mini Balance Evaluation Systems Test.** It measures dynamic balance, functional
299 mobility, and gait in neurological patients, including people with RRMS (80). The specific test
300 consists of 14 items, including four of the six segments (anticipatory postural adjustments, sensory
301 orientation, reactive postural control and dynamic gait) from the Balance Evaluation Systems Test.
302 The Mini Balance Evaluation Systems Test should be scored out of 28 points to include 14 items
303 that are scored from zero to two.

304 **2. Six Spot Step Test.** It is a timed walking test that involves kicking over a number of
305 targets placed along a 5m-path in which rely to some extent on vision and cognition (81). The Six
306 Spot Step Test is measured in the time domain replicating a complex range of sensorimotor
307 functions, part of which are lower limb strength, spasticity, coordination, as well as balance. We
308 will perform the specific test as it is described by Nieuwenhuis et al (2006) (81) and we will record
309 the mean time of the four runs as the final test result (82).

310 **3. Action Research Arm Test.** It is a 19-item observational measure used by
311 physiotherapists and other health care professionals to examine upper limb performance (i.e.,
312 coordination, dexterity and functioning) (83). Items covering the Action Research Arm Test are
313 categorized into four subscales (grasp, grip, pinch and gross movement) and arranged in order of
314 decreasing difficulty, with the most difficult task examined first, followed by the least difficult
315 task. The patient is sitting comfortable in front of a stable desk performing each task and the
316 performance is rated on a four-point scale, ranging from 0 (no movement) to 3 (movement
317 performed normally). We will record the total score for each upper limb separately as the final test
318 result.

319 **4. Isometric Dynamometer.** We will assess the isometric muscle force of major muscle
320 groups with the use of the muscle controller (Kinvent Biomechanique, Montpellier, France) which
321 is a dynamometer used in the evaluation and rehabilitation of muscle strength that provides real
322 time biofeedback (84). The patient lies (supine or prone) on a therapeutic bed and the
323 physiotherapist, with the use of the muscle controller, holds against the patient's limb as the patient
324 exerts a maximal force. The physiotherapist counters the force (make test) or tries to break the
325 contraction (break test) and the data will be stored using the KFORCE APP (Kinvent
326 Biomechanique, Montpellier, France). Shoulder flexors, extensors, rotators, horizontal adductors
327 and abductors adductors and abductors, elbow flexors and extensors are the major muscle groups
328 which will be evaluated. A separate value for each muscle group will be recorded in order to be
329 used in the visual and statistical analysis.

330 **5. Symbol Digit Modalities Test.** We will employ the oral form which assesses the
331 information processing speed (85). During the test, the participant will be given two minutes to
332 orally match symbols with digits as quickly as possible. The key (specifying which symbols are
333 assigned to which numbers) will be located at the top of a computer screen. The researcher will
334 instruct the participants that each symbol is paired with a digit. Next, the participant will be
335 instructed to perform the test by responding orally to each symbol. For example, the symbol “O”
336 is matched with the number 6, so the correct response would be to say “six”. The researcher
337 responsible for clinical assessments will record the participant’s responses directly on a computer
338 screen. The score is obtained by subtracting the number of errors from the number of items
339 completed in two minutes.

340 **6. Modified Fatigue Impact Scale.** It is a short questionnaire which requires the
341 participants to describe the effects of fatigue during the past four weeks (55) (S1. Appendix 1).

342 The Modified Fatigue Impact Scale consists of 21 questions which are subjectively rated from “0”
343 (low rate) to “4” (high rate) and it is also divided into three subscales (i.e., physical, cognitive, and
344 psychosocial). We will record the total score of the test as the final test result. The higher the score
345 is, the greater is the impact of fatigue in individual daily life. Although, to describe fatigue level
346 the Fatigue Severity Scale is more commonly used, we decided not use it because it describes
347 severe fatigue. Therefore, we will use the Modified Fatigue Impact Scale as the description of
348 participants` attribution of functional restrictions to fatigue symptoms.

349

350 **Analysis plan**

351 To investigate possible effects of our protocol we will follow recommended guidelines
352 (54), in which we will perform a separate analysis for each of the outcome measures, in all
353 experimental phases (i.e., baseline, intervention and follow up). We will perform a visual analysis
354 first, in order to determine whether there is a functional relationship between the intervention and
355 the outcome measures, and secondly, we will perform a quantitative analysis methods to evaluate
356 the magnitude of the intervention effect, provided there is evidence from the visual analysis (54).
357 We will perform all neurophysiological and clinical assessments to each participant according to
358 the number of data points during each phase (i.e., baseline, intervention, follow up) (Fig 1).

359 **TMS measures analysis**

360 Corticospinal plasticity will be determined through changes of the corticospinal excitability
361 and the central motor conduction time. Hence, we will quantify bilateral resting motor threshold,
362 MEP amplitude and latency, because each measure can assess different plastic changes across the
363 neuromotor axis and they can be used as a proxy of corticospinal plasticity. Resting motor

364 threshold (% maximum stimulator output) states the general excitability of the neuromotor axis in
365 the target muscle, amplitude (mV) expresses transynaptic activation of corticospinal neurons (86),
366 while latency (ms) is the time between the TMS onset and the MEP onset, which refers to the
367 integrity of the white matter fibers (87).

368 For both upper limbs, all neurophysiological measures (i.e., resting motor threshold, MEP
369 amplitude, latency) will be first calculated from each MEP trace and then averaged to get a single
370 value. These calculations will be done according to the different time points for each participant
371 in the baseline phase, at five time points in the intervention phase and at three time points in the
372 follow-up phase (Fig 1). In order to investigate possible changes in cortical excitability, we will
373 measure resting motor threshold and peak-to-peak amplitude throughout assessing MEPs (88) of
374 the Abductor Pollicis Brevis muscle, while measuring of latency will indicate possible changes in
375 central motor conduction time. Any changes in all measures across time points, will indicate
376 alterations in corticospinal plasticity (89). We will evaluate resting motor threshold using MTAT
377 2.0 (76) (available at <http://clinicalresearcher.org/software.htm>) and to investigate possible
378 changes in individual corticospinal plasticity of each participant, we will calculate bilaterally the
379 difference between the mean values of each phase (73,90). On the other hand, from each stimulus
380 response during the suprathreshold stimulation (i.e., 120% of resting motor threshold) (89), we
381 will calculate offline the MEP peak-to-peak amplitude and latency. To define central motor
382 conduction time (ms), we will subtract the peripheral conduction time ((F wave latency + M wave
383 latency – 1)/2) from the central conduction time (MEP latency). The F wave is the muscle response
384 elicited by activation of the alpha motor neuron, while the M wave is the direct response of the
385 muscle (66). A prolonged central motor conduction time indicates damage of large fibres,
386 demyelination of central motor pathways or slow summation of descending excitatory potentials

387 in the corticospinal tract evoked by TMS (66,69). To standardise all latencies (i.e., MEP, F and M
388 wave), we will use a visual inspection from stimulation onset to response onset, performed from
389 the same investigator so to ensure reliability of the study across all time points. To define possible
390 changes in central motor conduction time, we will evaluate bilaterally the difference between the
391 mean values of each phase.

392 **Clinical measures analysis**

393 For each clinical measure (i.e., balance, gait, cognitive function, bilateral hand dexterity
394 and strength) and for the Modified Impact Scale we will calculate the values from each time point
395 across all phases (i.e., baseline, intervention, follow-up) and then we will evaluate the average of
396 them, so to get a single mean value for each measure and for each phase (mean baseline; mean
397 intervention mean follow-up). To investigate the association between the intervention protocol and
398 clinical condition, we will calculate the differences between phases' mean values (i.e., mean
399 baseline; mean intervention; mean follow up), reflecting to the degree of change in clinical
400 condition following in-phase bilateral exercises.

401

402 **Visual analysis**

403 Two assessors will systematically measure each outcome measure across time, inter-
404 assessor agreement will be calculated on at least twenty percent of the data points in each
405 condition. The minimum acceptable inter-assessor agreement will be set to 0.8 (56).

406 Initially, a visual analysis will be conducted and presented graphically in a spaghetti plot,
407 in order to define whether there is a functional relation between the intervention and the outcome
408 measures (54). During the visual analysis, six features of the research design graphed data will be
409 examined: level, trend, stability, immediacy of the effect, overlap, and consistency. Over the

410 within-phase examination an evaluation of level, trend and stability will be examined. Level will
411 be reported from the mean score of each dependent variable and trend will determine whether the
412 data points are monotonically decreased or increased. Stability will be estimated based on the
413 percentage of data points falling within 15% of the phase median, if this is higher than 80% then
414 we assume that this criterion is met. Additionally, over the between-phase examination an
415 evaluation of overlapping data among baseline and intervention phases, consistency of data
416 patterns and immediacy of effect will be performed (54). The Percentage of Non-overlapping Data
417 index will be used to quantify the proportion of data points in the intervention phase that do not
418 overlap with the baseline phase (91) and the test statistic will be calculated using the Improvement
419 Rate Difference as an effect size index. Immediacy of the effect will be examined by comparing
420 changes in level between the last three data points of one phase and the three first data points of
421 the next phase. Furthermore, consistency of data patterns involves the observation of the data from
422 all phases within the same condition, with greater consistency expressing greater causal relation.
423 Each feature will be assessed individually and collectively across to all participants and to all
424 phases. Consequently, if the intervention protocol is the sole determinant of improvement, we
425 expect to find indicators of improvement only at the intervention phase.

426

427 **Statistical analysis**

428 For each of the outcome variables that the visual analysis indicates a potential functional
429 effect, a quantitative analysis will be performed to estimate the effect size. This analysis will be
430 performed for each variable at which a significant trend is shown as described in the previous
431 section. In order to estimate the individual-level effect sizes, we will use three different methods,
432 as suggested by ‘What Works Clearinghouse’ (56), the standardized mean difference (Cohen’s d),

433 the standardized mean difference with correction for small sample sizes (Hedges' g) and piecewise
434 regression analysis which does not only reflect the immediate intervention effect, but also the
435 intervention effect across time. Multilevel modelling, which is recommended by the 'What Works
436 Clearinghouse' and the single case educational design, specific mean difference index will be used
437 to estimate the magnitude of the effect across cases and compared to the effect obtained by the
438 single level estimates (54).

439 For all the different neurophysiological parameters and clinical conditions, evaluated
440 separately, the null hypothesis is that "there is no improvement from the proposed intervention",
441 thus participants' responses are independent from the condition (baseline versus intervention)
442 under which they were observed. The alternative hypothesis is that "the neurophysiological
443 parameters and /or the clinical condition of the participants will be affected by the specific
444 intervention", again assessed separately. We will reject the null hypothesis if the p value is smaller
445 than 0.05. All tests will be two sided. Statistical analysis will be performed using the statistical
446 software R (<https://www.r-project.org/>).
