Summary paragraph

An outbreak of acute hepatitis of unknown aetiology in children was first reported in Scotland in April 2022.¹ Cases aged <16 years have since been identified in 35 countries.² Here we report a detailed investigation of 9 early cases and 58 control subjects. Using next-generation sequencing and real-time PCR, adeno-associated virus 2 (AAV2), was detected in the plasma of 9/9 and liver of 4/4 patients but in 0/13 sera/plasma of age-matched healthy controls, 0/12 children with adenovirus (HAdV) infection and normal liver function and 0/33 children admitted to hospital with hepatitis of other aetiology. AAV2 typically requires a coinfecting ‘helper’ virus to replicate, usually HAdV or a herpesvirus. HAdV (species C and F) and human herpesvirus 6B (HHV6B) were detected in 6/9 and 3/9 affected cases, including 3/4 and 2/4 liver biopsies, respectively. The class II HLA-DRB1*04:01 allele was identified in 8/9 cases (89%), compared with a background frequency of 15.6% in Scottish blood donors, suggestive of increased susceptibility in affected cases. Acute non-A-E paediatric hepatitis is associated with the presence of AAV2 infection, which could represent a primary pathogen or a useful biomarker of recent HAdV or HHV6B infection. Population and mechanistic studies are required to explore these findings further.
Main text

**Hepatitis outbreak in Scottish children**

In April 2022, a cluster of five young children presented with jaundice and acute severe hepatitis of unknown aetiology were reported by several hospital sites in Scotland. In response, Public Health Scotland (PHS) convened a National Incident Management Team (IMT), alongside the UK Health Security Agency (UK HSA) and academic partners (ISARIC4C Investigators) to coordinate further investigations and the public health response. As of 4 July 2022, 36 children aged 10 years and under with acute unexplained non-A to E hepatitis have been confirmed in Scotland, one of whom required liver transplantation (Figure 1a). Elsewhere in the UK, 186 confirmed cases have been reported and 14 children have required liver transplantation. Globally, the World Health Organisation (WHO) has reported over 1010 probable cases fulfilling their case definition in 35 countries. Clinical investigations in Scotland excluded all expected causes of acute hepatitis including hepatitis A, B, C and E viruses, HSV, CMV and EBV. Adenovirus (HAdV) was identified by PCR in 53.1% (17/32) of tested cases. Recent reports from the UK and the USA have also identified HAdV to be present in the majority of cases in two cohorts of children. A spike of HAdV infections in Scotland predominantly affecting children <5 years also directly preceded the outbreak of unexplained hepatitis (Figure 1b). SARS-CoV-2 PCR was positive in 16.7% (6/36 tested cases). A rise in COVID-19 cases in the community preceded the spike in non-A-E hepatitis by around two years (Figure 1c). Human herpesvirus 6 (HHV6A and HHV6B) infections were not detected at higher levels during 2021 or 2022 (Figure 1d).
To investigate the aetiology of the acute hepatitis cases, we recruited nine of the earliest affected children who presented to hospital between 14 March and 4 April 2022 into the International Severe Acute Respiratory and Emerging Infections Consortium (ISARIC) WHO Clinical Characterisation Protocol UK (CCP-UK) [ISRCTN 66726260]. Ethical approval was given by the South Central–Oxford C Research Ethics Committee in England (13/SC/0149), the Scotland A Research Ethics Committee (20/SS/0028), and the WHO Ethics Review Committee (RPC571 and RPC572). Control samples were obtained from the Diagnosis and Management of Febrile Illness using RNA Personalised Molecular Signature Diagnosis study cohort (DIAMONDS; https://www.diamonds2020.eu). This study recruited children presenting with suspected infection or inflammation. Patients were recruited with the informed written consent of parents or guardians. The DIAMONDS study was approved by the London–Dulwich Research Ethics Committee (20/HRA/1714).

Control subjects were restricted to children recruited in the UK between January 2020 and April 2022. Three comparison groups were identified: Group 1, sera from 13 age-matched healthy children (10 male, 3 female; age range 3-5 years); Group 2, 12 children (8 male, 4 female; age range 1-4 years) with PCR-confirmed HAdV infection and normal transaminases (n=12); Group 3, 33 children (18 male, 15 female; age range 2-16 years) with raised transaminases who were HAdV PCR negative. Within Group 3, 15 children required critical care for ventilatory or cardiovascular support. There was no significant difference in age between cases and healthy controls, but some control samples were sampled earlier than case samples (January 2020-April 2022 versus March-April 2022). Children with HAdV infection with normal liver function were younger (median age 1.6 years; interquartile range (IQR) 1.1-3.3 years, p<0.001), and children with deranged liver function and no adenoviral infection were...
older (median age 9.2 years; IQR 6.7-13.6 years, p=0.001), compared to cases. (Supplementary Table 1).

Clinical presentation

The median age of case patients was 3.9 years (IQR: 3.4 to 5.1 years). Four of the nine children were male, and all were of white ethnicity. All were admitted to hospital and met the PHS case definition for confirmed acute hepatitis, with a serum transaminase >500 IU/L (AST or ALT) without any known cause, aged 10 years or under and presenting after 1st January 2022. The majority of the children reported a preceding subacute history of abdominal pain, diarrhoea and vomiting, occurring between 1 to 11 weeks prior to acute hepatitis. None of the cases were immunocompromised and none had received COVID-19 vaccination. All routine blood tests for viral hepatitis, including hepatitis A, B, C, E, Epstein-Barr virus (EBV), cytomegalovirus (CMV), human herpes virus (HHV) 6/7 and herpes simplex virus (HSV) were negative (Supplementary Table 2). One case had weakly positive antinuclear antibodies (ANA; titre 1:80), but otherwise autoimmune markers, [immunoglobulins, antinuclear antibodies (ANA), anti-mitochondrial antibodies (AMA), anti-smooth muscle antibodies (ASMA), anti-liver-kidney microsomal (anti-LKM) antibody and tissue transglutaminase antibody (TTG)] were negative. Four of the children had liver biopsies, which all showed evidence of lobular hepatitis with periportal and interface inflammation, bile duct proliferation and ballooning of hepatocytes, but no evidence of confluent fibrosis (Figures 1e-j). Two cases required transfer to a specialist liver unit due to significant synthetic liver dysfunction. Both improved with steroid therapy and neither required liver transplantation. There were no deaths and the median duration of hospital stay was 10 days (range 5-32 days).

Genome sequencing
As the epidemiology was in keeping with the emergence of an infectious pathogen, we undertook metagenomic and target enrichment sequencing and real-time PCR on all available clinical samples of cases, including plasma (n=9), liver biopsies (n=4), throat swabs (n=6), faecal samples (n=7) and a rectal swab (n=1), obtained between 7 to 80 days from initial symptom onset (Figures 2a-d, Supplementary Tables 3-5). Metagenomic sequencing was carried out using protocols designed to identify both RNA and DNA viruses. Semi-agnostic target enrichment sequencing was also performed using VirCapSeq-VERT Capture probes that target the genomes of 207 viral taxa known to infect vertebrates (Supplementary Information). The most frequently detected viral genomes in affected patient plasma were adeno-associated virus 2 (AAV2) in 9/9 patients (range 152-24,968 sequence reads per million) and at a lower read count, HAdV-F41 or HAdV-C (types 1, 2, 5 and 6 could not be distinguished reliably due to low read counts) in 6/9 patients (range 0-1.66 reads per million). HHV6B was detected at low level in the liver biopsy samples of 2/4 patients by PCR and 3/4 plasma samples by NGS but was not confirmed by PCR in plasma in 9/9 patients (Figures 2e, 3a).

AAV2 was detected in 9/9 serum samples and 4/4 liver biopsies, 1/7 faecal, 1/1 rectal and 1/6 throat swab samples. Near full genomes of AAV2 were detected in all 9 patients and contained two large open reading frames corresponding to rep and cap, flanked by ITR regions. Seven distinct lineages of AAV2 were noted (Figure 4a) within a cluster containing 4 AAV2 genomes detected in France between 2004 and 2015. Two of three identical sequences were known to have come from a single household and the third occurred around the same time but was not known to be otherwise linked. Several mutations within the VP1-3 genes were noted to be over-represented in the sequences derived from patients with hepatitis when compared with reference sequences (Figure 4c). Notably, 9 of the capsid gene mutations over-
represented in these cases (V151A, R447K, T450A, Q457M, S492A, E499D, F533Y, R585S and R588T) are associated with a sub-lineage of AAV2 (AAVv66) that has an altered phenotype, including substantial evasion of neutralising antibodies directed against wild-type AAV2, enhanced production yields, reduced heparin binding and increased virion stability. Intrathecal injection of AAVv66 in mice resulted in widespread CNS transduction compared with more localised spread in mice injected with wildtype AAV2.8

HAdV was detected in 3/9 plasma samples, 3/4 liver biopsies, 2/6 throat swabs, 4/7 faecal samples and 1/1 rectal swab (Figure 2b; Supplementary Table 3). The lower detection of HAdV by PCR compared to enrichment sequencing likely reflects slightly lower sensitivity of the PCR assay. However low numbers of positive samples using both assays may reflect the fact that plasma is a suboptimal sample type for HAdV detection (whole blood samples were unavailable). A full genome of HAdV-F41 was retrieved from a faecal sample (accession number pending) and was found to be closest to two genomes reported from Germany in 2019 and 2022 (Figure 2b). As described above, HHV6B was detected at low read number (0.41-3.89 reads per million) in 3 out of 4 plasma samples (Figure 3a, Supplementary Table 4). The remaining clinical samples were excluded from analysis for HHV by sequencing because murine CMV had been added as an extraction control during routine clinical investigation. All 9 plasma samples tested negative by PCR for HHV6, HSV, CMV and EBV. Two liver biopsy specimens tested positive for HHV6 (Ct 33 and 36). Contigs matching to other known human pathogens, including human coronavirus NL63, rhinovirus C, enterovirus B, human parainfluenza virus 2 and 3, norovirus, as well as other beta- and gammaherpesviruses were also detected although not consistently across cases (Supplementary Table 2). These were detected by both sequencing and PCR.
To investigate the presence of AAV2 and the candidate helper viruses HAdV and HHV6B in case samples, we undertook a series of case-control studies using plasma by sequencing and by real-time PCR (Figures 2b-e, 3a). Higher read counts of HAdV (p=0.0545), AAV2 (p<0.001) and HHV6B (p=0.0059) were found in cases versus healthy controls (Supplementary Figures 1a,1b). Metagenomic and target enrichment sequencing from the 13 age-matched healthy control samples (group 1) revealed no evidence of AAV2, HAdV or HHV6B in plasma, although low read counts of EBV, CMV and HHV6A were detected (Figure 3a, Supplementary Figure 1c-j). 12 HAdV-infected controls (10 diagnosed by nasopharyngeal aspirate, 1 by nose swab and 1 by stool) with normal liver function (group 2) were found to have no evidence of AAV2. HAdV reads were also detected in 6/12 plasma/serum samples, and 9/12 of this group had a herpesvirus detected, including 2/12 with detectable numbers of HHV6B reads (1050-5062 reads per million), confirmed by PCR (Figure 2a; Supplementary Table 6; Supplementary Figure 1). In keeping with the possibility of reactivation of HHV6B, 6/12 of this control group had been admitted to hospital with a critical illness.

Real-time PCR

To quantify the level of AAV2 and to further investigate the presence of the helper viruses HAdV and HHV6B, we carried out real-time PCR in case plasma and control sera/plasma. We also included a third control group of patients with hepatitis of alternative aetiology, half of whom had been admitted to critical care (Figures 2c-e). Significance differences between groups for Ct values and viral loads/ml of plasma were calculated using the Mann-Whitney test. AAV2 PCR of plasma from 9/9 cases was positive with a median estimated copy number of 8,058,879 copies/ml (Figure 2c; Supplementary Figure 2). 2/9 case plasma were positive
for HAdV-F41 by PCR (Figure 2d), and all tested negative by PCR for HHV6 DNA (Figure 2e).

**SARS-CoV-2 infection**

Routine clinical investigation detected SARS-CoV-2 nucleic acid in nasopharyngeal samples from 2/9 children, one of whom was also seropositive. The other developed infection after the onset of hepatitis. SARS-CoV-2 was not detected by PCR and sequencing in any clinical samples, including liver samples, in cases or controls. Nevertheless, to investigate the possibility that unexplained hepatitis in children might relate to a preceding SARS-CoV-2 infection or other seasonal coronaviruses, we carried out serology. IgG antibody titres were measured quantitatively against SARS-CoV-2 trimeric spike (S) protein, N-terminal domain (NTD), receptor binding domain (RBD) and nucleocapsid (N), and the human seasonal coronaviruses (HCoVs) 229E, OC43, NL63 and HKU1. Electrochemiluminescence assay (MSD-ECL) for coronavirus-specific IgG revealed high levels of prior exposure to seasonal coronaviruses; NL63 (9/9) and OC43 (7/9) (Supplementary Figure 3a). In comparison, plasma from 5/9 children displayed reactivity with HKU1 and 3/9 with 229E. Plasma from three children reacted with SARS-CoV-2 N, a fourth was considered weak positive in comparison with the reference range of known negative individuals (Supplementary Figure 3b). This child was one of 3/4 of the N-positive children displaying reactivity with S, NTD and RBD, confirming likely SARS-CoV-2 exposure. Plasma from the fourth child reacted with N only, while plasma from an additional two children reacted with S, NTD and RBD only (no N reactivity) in keeping with exposure to natural infection in the absence of vaccination. In summary, 6/9 (67%) of the children displayed evidence of prior exposure to SARS-CoV-2; this level was comparable to SARS-CoV-2 seroprevalence in children aged 5-11 years in Scotland.
between 14th March and 4th April 2022 (time period when clinical samples of cases were obtained), reported as between 59% (95% CI 50.6-71.2) and 67% (56.2-77.6%).

**HLA typing**

To investigate the possibility that some children might be more susceptible to non-A-E hepatitis, cases and local controls (all of white ethnicity) were genotyped using high resolution typing for all HLA loci (HLA-A, B, C, DRB1, DRB3/4/5, DQA1, DQB1, DPA1 and DPB1) using the AllType™ FASTplex™ NGS Assay (One Lambda). We analysed HLA allele positivity in the nine cases plus an additional 11 ISARIC CCP-UK study patients (n=20 in total) compared to 64 Scottish platelet apheresis donor controls. Associations were observed for the following alleles; DRB1*04:01 (OR 11.8 (95% CI 4.43-32.13), p = 1.19 x 10^-9), DQA1*03:03 (OR 10.64 (4.07-28.18), p = 3.8 x 10^-9) and DQB1*03:01 (OR 6.16 (2.49-15.21), p = 3.75 x 10^-6). The strength of associations and the known linkage disequilibrium between HLA-DRB1*04:01 and associated alleles at other HLA loci indicates that DRB1*04:01 is the primary HLA associated allele. In patients, the HLA-DRB1*04:01 allele frequency was 0.50 and in local controls was 0.078. As a further reference, in 599,410 British/Irish North-West European (BINWE) individuals on the Anthony Nolan register, the frequency of DRB1*04:01 is 0.114. Of the nine patients in which metagenomic and target enrichment sequencing was undertaken, 8/9 carried the HLA-DRB1*04:01 allele and one carried the HLA-DR4 allele, DRB1*04:07.

**Conclusions/final statements**

AAV2 detected independently by sequencing and by real-time PCR was present at significantly higher frequency in cases of paediatric non-A-E hepatitis than controls. That this occurs in the context of an increased frequency of the DRB1*04:01 allele when compared to a local blood
donor control population requires further investigation, but points to a T helper cell-mediated pathological response triggered by exposure to HAdV and/or AAV2 infection.

AAV2 is a small non-enveloped single-stranded DNA virus of 4,675 nucleotides belonging to the species adeno-associated dependoparvovirus A (genus Dependoparvovirus, family Parvoviridae)\textsuperscript{11}, first described in 1965 and occurs in up to 80% of the adult population, seroconversion occurring in early childhood following respiratory infection\textsuperscript{12}. In one prospective study in the USA, the earliest seroconversion to AAV2 infection occurred in a 9-month-old child and the sero prevalence increased from 24.2% to 38.7% in 3 and 5-year-old children, respectively\textsuperscript{13}. This age range coincides with that of the cases in this study, raising the possibility of illness relating to primary infection rather than reactivation. Dependoparvoviruses rely on coinfection with a helper virus for replication, most commonly HAdV or a herpesvirus. The majority of clinical samples taken at presentation with hepatitis were obtained more than 20 days after initial symptom onset, which could explain the absence of a helper virus in some samples, and low viral loads (high Ct value) in positive samples. We detected two candidate helper viruses at low level in the cases; HAdV and HHV6B in 6/9 and 3/9 cases respectively (HHV6 was detected only by NGS at very low read counts and was not confirmed by PCR in any of the cases). HHV6B was also present in two control groups that included children with severe HAdV infection and children with hepatitis of alternative aetiology. As HHV-6 can establish latency and can integrate its genome into the human chromosome, it may reactivate following concomitant illness (or immunosuppression) and may represent either an opportunistic bystander or a pathogen.

We hypothesise that AAV2 may be directly implicated in the pathology of non-A-E hepatitis in children, following transmission as a co-infection with HAdV (or HHV6, although this is
much less likely) or as a result of reactivation following HAdV or HHV6 infection. Class II HLA type may contribute to disease susceptibility. In keeping with an immune-mediated aetiology directed against AAV2-infected hepatocytes, hepatitis associated with the emergence of a CD8+ cell-mediated response directed against the AAV2 viral capsid (VP1) was reported in early trials of AAV2 when used as a vector for gene therapy.\textsuperscript{14-16} An alternative explanation is that AAV2 may be a useful biomarker of infection with HAdV (that may be the primary pathogen) that persists for a shorter time than AAV2. Most of our cases developed gastroenteritis symptoms (vomiting and diarrhoea) lasting several days, several weeks before the onset of jaundice. The opportunity to detect virus by sequencing was therefore likely reduced, as these samples were collected at a later stage. Further, whole blood samples would have been likely to increase the sensitivity of detection, but only plasma samples were available. We consider this alternative hypothesis to be less likely because we did not detect AAV2 in a control group of children with HAdV infection who had normal liver function.

HAdV41 is a common cause of diarrhoea in young children\textsuperscript{17} and adenovirus-associated hepatitis has been described, particularly among immunocompromised individuals.\textsuperscript{18} However, it has not previously been associated routinely with severe hepatitis. In the recent outbreaks of unexplained hepatitis in children, it has been inconsistently reported.\textsuperscript{4-6,19-21} HHV6B is a human herpesvirus that is associated with the childhood illness roseola infantum (sixth disease) and a self-limiting otherwise non-specific febrile illness.\textsuperscript{22} Seroconversion usually occurs by 2 years of age and hepatitis occasionally occurs in immunocompetent individuals.

We investigated the possibility that unexplained cases of hepatitis may be linked to prior COVID-19 infection. Direct SARS-CoV-2 liver injury seems unlikely, since few of our cases (2 of 9) were SARS-CoV-2 PCR-positive on admission, and we did not identify SARS-CoV-
Further, the SARS-CoV-2 antibody positivity in hepatitis cases was within community positivity rates at that time. This is in keeping with a case-control analysis by UKHSA reporting no difference in SARS-CoV-2 PCR positivity between hepatitis cases and children presenting to emergency departments between January and June 2022. Nevertheless, we cannot fully exclude a post-COVID-19 immune-mediated phenomenon in susceptible children.

There are several limitations to this study. Firstly, the presence of AAV2 in cases but not controls may have arisen due to seasonal variation in AAV2 transmission, as some controls were sampled earlier than cases. Secondly, the presence of AAV2 in cases is an association and may not represent direct aetiology; rather the AAV2 may be a useful biomarker of recent HAdV (or less likely HHV6B) infection. We do not consider it likely that AAV2 simply represents a marker of liver damage because it was not present in cases of severe hepatitis of alternative aetiology. Thirdly, while the strong association of the HLA-DRB1*04:01 allele, known to be associated with autoimmune hepatitis and extra-articular manifestations of rheumatoid arthritis, may represent a disease susceptibility gene, local population structure could result in an over-estimate of significance. Nonetheless it is plausible that an HAdV infection, along with a coinfecting or reactivated AAV2 infection has resulted, for a proportion of children who are more susceptible (due to the class II HLA allele HLA-DRB1*04:01), in a more severe outcome than might normally be expected for these commonly circulating viruses. The recent clustering of cases may have arisen in part because of changes in exposure pattern to HAdV, AAV2 and HHV6B as a result of the COVID-19 pandemic. Faecal HAdV usually follows seasonal trends with maximal rates of detection in younger age groups. However, the circulation of respiratory viruses was interrupted in 2020 by the implementation of non-pharmaceutical interventions, including physical distancing and travel restrictions, instituted
to mitigate SARS-CoV-2 transmission. These measures may have created a pool of susceptible
younger children, resulting in much higher rates of HAdV and potentially AAV2 circulation in
this population of naïve children when the COVID-19 restrictions were relaxed.

Larger case-control studies are urgently needed to investigate the role of AAV2, HAdV,
HHV6B and HLA type in the aetiology of unexplained non-A-E paediatric hepatitis. Retrospective testing of samples from cases of unexplained hepatitis in children is also
indicated. Ongoing work to measure IgM and IgG responses against AAV2, HAdV and
HHV6B may help to delineate whether the AAV2 has been acquired as a primary co-infection
or reactivation.

Figure 1: Epidemiology and histology of liver biopsies in Scottish children with AAV2 and HAdV-associated hepatitis (a) Emergence of acute non-A to E hepatitis in children

Cases of non-A-E hepatitis in children 10 years and under in Scotland, 11 January to 20 June 2022 (pink).^ Cases of HAdV (children <5 years: red, children 5-10 years: purple) (b), SARS-CoV-2 (black) (c) and HHV6 (blue) (d) in children aged 10 years and under in Scotland January 2019 to June 2022. The histology of Case 3 (CVR3) is shown in panels (e-j). A low-power liver biopsy image (e) showing expansion of the portal tracts by inflammatory cells (1), interface hepatitis (2), feathering (ballooning) change of hepatocytes (3) and apoptotic hepatocytes (4). Mild steatosis is present in some zone 2 hepatocytes (5). A medium power view of the same biopsy (f) illustrates an affected portal tract showing a mixed infiltrate of inflammatory cells (lymphocytes, plasma cells, eosinophils and neutrophils). Vessels and bile ducts are preserved. A high-power picture (g) of the liver parenchyma showing feathering (ballooning) change in the hepatocytes (1), focal mild steatosis (2), focal bile canaliculi plugging (3) and lipofuscin pigment (4). An apoptotic hepatocyte (h) is highlighted with an asterisk *. A reticulin stain of the same biopsy (i) highlights an increased density of fibres in areas of inflammation and some change of the zone 2 parenchyma. A Masson trichrome stain showing collagen in blue (j) within portal tracts and mild staining extending around some hepatocytes.
Figure 2. (a) Heatmap of HAdV and AAV-2 reads detected in hepatitis cases by target enrichment sequencing. Samples obtained for routine clinical investigation (plasma, liver, faeces, rectal and throat swab) were retrospectively sequenced following DNA or RNA extraction. AAV2 read counts are shown from 0->100 reads/million in green (upper row) and HAdV read counts are shown from 0->10 reads/million in red (lower row). (b) Heatmap of viral reads from plasma in cases and plasma/sera from controls. Plasma samples from cases, and plasma or sera samples from children with HAdV infection and age-matched healthy controls were sequenced following DNA or RNA extraction. AAV2 read counts are shown from 0->100 reads/million in green and HAdV read counts are shown from 0->10 reads/million in red. The number of days between initial symptom onset and sample are indicated. (c) AAV2 real-time PCR in cases versus controls. The estimated detection limit of the assay (Ct=31.9) is shown (dotted line) Error bars represent median. Statistical analysis was performed using Mann-Whitney test. (d) HAdV41 real-time PCR in cases versus controls. (e) HHV6 real-time PCR in cases versus controls.
Figure 3 Herpesviruses detected in cases and controls. (a) Results are shown from target enrichment sequencing, PCR and IgM serology. Sequencing read counts are shown in blue as a heatmap from 0-100 reads per million. Ct values are highlighted in orange from 0-40. As the plasma samples from patients 1-5 had a Murid herpesvirus as a spike in control, the herpesvirus content of these samples was not analysed.
Figure 4 (a) Phylogeny of AAV2 genomes from cases 1-9. The nine AAV2 genome sequences generated from the plasma samples via target enrichment (highlighted in red) were aligned with a range of the closest AAV sequences from La Bella et al.\textsuperscript{25} and Cordey et al.\textsuperscript{26} IQ-TREE 2 was used to find the optimal model (TIM+F+R3) and create a maximum
likelihood (ML) phylogenetic tree with 1000 bootstrap replicates (displayed on the branches).

The tree is midpoint rooted. AAV2 reference sequences are denoted by accession number, country and year of sampling. **(b) Phylogeny of HAdV41 genome from case 5** A near-full HAdV41 genome sequence from the faecal sample of patient 5 (highlighted in red) was combined with complete genomes of HAdV41 from GenBank. After alignment with MAFFT, IQ-TREE 2 was used to determine the optimal evolutionary model (K2P+R2) and to construct a ML phylogenetic tree with 1000 bootstrap replicates. The tree is midpoint rooted. HAdV41 reference sequences are denoted by accession number, country and year of sampling.

**(c) Key mutations and hierarchical clustering of AAV2 genomes** Mutations in published AAV2 sequences are highlighted in (blue) and case sequences (green) **(d)** **Mutations over-represented in cases versus controls** Mutations in VP1-3, Rep78 and 52 and AAP are highlighted by % representation in case sequences (green) and published sequences (blue)
Methods

ISARIC CCP-UK recruitment & DIAMONDS/ study

Ethical approval for the ISARIC CCP-UK study was given by the South Central–Oxford C Research Ethics Committee in England (13/SC/0149), the Scotland A Research Ethics Committee (20/SS/0028), and the WHO Ethics Review Committee (RPC571 and RPC572). Children aged <16 years were recruited by written informed consent (parent or guardian) from the ISARIC WHO CCP-UK cohort admitted to hospital with elevated transaminases (defined as ALT >400 iU/L and/or AST >400 iU/L) that was not due to viral hepatitis A-E, autoimmune hepatitis or poisoning. Control samples were obtained from children (aged <16 years) recruited to the Diagnosis and Management of Febrile Illness using RNA Personalised Molecular Signature Diagnosis (DIAMONDS), an ongoing multi-country study that aims to develop a molecular diagnostic test for the rapid diagnosis of severe infection and inflammatory diseases using personalised gene signatures (ISRCTN12394803). Ethical approval was given by London-Dulwich Research Ethics Committee (20/HRA/1714). Controls included healthy controls (n=13), children with PCR-confirmed adenoviral infection with normal transaminases (n= 12), and children with raised transaminases without adenoviral infection (n=33), recruited between 19 May 2020 to 8 January 2022.

Viral PCR

RNA extraction was carried out using the Biomerieux Easymag generic protocol. 300ul of plasma or sera was extracted and eluted into 80 ul of water.

AAV2 quantitative PCR was performed to detect a 62bp amplicon of the AAV2 inverted terminal repeat region (ITR) as previously described using the forward ITR primer 5'
GGAACCCCTAGTGATGGAGTT-3') and the reverse ITR primer 5’-CGGCCTCAGTGAGCGA-3'). The AAV2 ITR hydrolysis probe was labelled with fluorescein (6FAM) and quenched with Black Hole quencher (BHQ) 5’-[6FAM]- CACTCCCTCTCTGCGCGCTCG-[BHQ1]3’). AAV2 primers and probe were synthesised by Merck Life Sciences UK Limited, United Kingdom. Quantitative PCR analysis was performed using the ABI7500 Fast Real-Time PCR system (Applied Biosystems). LUNA Universal One-Step RT PCR kit (New England Biolabs) was used for the amplification and detection of the AAV2 ITR target. qPCR reactions were performed in a 20µl volume reaction (Luna Universal One-Step reaction mix, Luna WarmStart RT enzyme mix, 400nM forward and reverse primers, 200nM AAV2 ITR probe and 1.2-2.5µl of template DNA) as per manufacturer’s instructions. To quantify the number of copies, serial dilutions of plasmid containing the 62bp ITR product were used to generate a standard curve which was then used to interpolate the copy number of AAV2 copies in the samples. Wells with no template were used as negative controls. qPCR reactions were performed in triplicate. The qPCR program consisted of an initial reverse transcription step at 55 C for 10 minutes, an initial denaturation at 95 C for 1 minute followed by 45 cycles 95 C denaturation for 10 seconds and extension at 58 C for 1 minute. A qPCR detection limit of 31.9 was calculated as the threshold Ct value at the last dilution of DNA standards that were within the linear range.

The West of Scotland Specialist Virology Centre, NHS Greater Glasgow and Clyde conducted diagnostic real-time PCR with reverse transcription to detect HAdV, SARS-CoV-2-positive samples and other viral pathogens associated with hepatitis (e.g. Hepatitis A-E), following nucleic acid extraction utilizing the NucliSENS easyMAG and Roche MG96 platforms. HHV6\(^2\)8 and HAdV41\(^2\)9 were tested by qPCR as previously described using Invitrogen platinum qPCR mix (Cat no 11730-025) and Quanta Biosciences qPCR mix Mastermix.
(Cat.No. 733-1273) respectively on an ABI7500 and amplified for 40 cycles. A 6ul extract was amplified in a total reaction volume of 15ul.

**Measurement of antibody response to coronaviruses by electrochemiluminescence**

IgG antibody titres were measured quantitatively against SARS-CoV-2 trimeric spike (S) protein, N-terminal domain (NTD), receptor binding domain (RBD) or nucleocapsid (N), and the human seasonal coronaviruses (HCoVs) 229E, OC43, NL63 and HKU1 using MSD V-PLEX COVID-19 Coronavirus Panel 2 (K15369) and Respiratory Panel 1 (K15365) kits. Multiplex Meso Scale Discovery electrochemiluminescence (MSD-ECL) assays were performed according to manufacturer instructions. Samples were diluted 1:5000 in diluent and added to the plates along with serially diluted reference standard (calibrator) and serology controls 1.1, 1.2 and 1.3. Plates were read using a MESO Sector S 600 plate reader. Data were generated by Methodological Mind software and analysed using MSD Discovery Workbench (v4.0). Results are expressed as MSD arbitrary units per ml (AU/ml).

**Metagenomic sequencing**

Residual nucleic acid from 27 samples (9 patients with a combination of plasma, liver, faeces, rectal and throat/nose samples), 12 HAdV-positive and 13 healthy controls (control samples were either plasma or sera) underwent metagenomic next-generation sequencing at the CVR. Briefly, each nucleic acid sample was split in two library preparations, to improve the chances of detecting RNA and DNA viruses. The protocol applied for improved detection of RNA viruses included treatment with DNaseI (Ambion DNase I, ThermoFisher), ribosomal depletion (Ribo-Zero Plus rRNA Depletion Kit, Illumina), except for plasma samples, reverse transcription (SuperScript III, Invitrogen) and double-strand DNA synthesis (NEBNext® Ultra™ II Non-Directional RNA Second Strand Synthesis Module, NEB). The protocol
applied to detect DNA viruses included partial removal of host DNA (NEBNext® Microbiome DNA Enrichment Kit, NEB). Following this, both sets of samples were used to prepare libraries using the KAPA LTP kit (Roche) with unique dual indices (NEBNext® Multiplex oligos for Illumina, NEB). The resulting libraries were pooled in equimolar amounts and sequenced using a NextSeq500 (Illumina) to obtain paired end reads using 150X150 cycles.

**Target enrichment sequencing**

Following on the library preparation step described above, DNA and RNA derived libraries were pooled separately and were incubated with the VirCapSeq-VERT Capture Panel probes (Roche) following the manufacturer’s guidelines. The Roche VirCapSeq-VERT Capture Panel covers the genomes of 207 viral taxa known to infect vertebrates (including humans). Enriched DNA and RNA-derived libraries were further amplified using 14 PCR cycles, pooled and sequenced using a NextSeq500 (Illumina) to obtain paired end reads using 150X150 cycles.

**Bioinformatics analysis**

Reads for each sample were first quality checked, Illumina adapters were trimmed using Trim Galore (https://github.com/FelixKrueger/TrimGalore), and reads were then mapped to the human genome using BWA-MEM (https://github.com/lh3/bwa). Only reads that did not map to the human genome were used for metagenomic analyses. Non-human reads were then *de novo* assembled using MetaSPAdes (https://github.com/ablab/spades) to generate contigs for each sample. Contigs were then compared against a protein database of all NCBI RefSeq organisms (including virus, bacteria, eukaryotes) with BLASTX using DIAMOND (https://github.com/bbuchfink/diamond). In addition, non-human reads for each sample were
aligned to a small panel of HAdV NCBI RefSeq genomes (HAdV-A, B1, B2, C, D, E, F, 1, 2, 5, 7, 35, 54 as well as HAdV-F41).

The nine AAV2 near-complete genome contigs from the plasma samples were assembled and were compared with sequences in GenBank using BLASTN (nt database); each AAV2 had numerous close hits (exhibiting >95% similarity across 95% of the genome) with various existing AAV2 sequences, those most closely related were reported in a recent publication\textsuperscript{25} A representative range of AAV2 sequences were selected and combined with the AAV sequences de novo assembled here, aligned with MAFFT, the terminal ends of the alignment were trimmed off, and IQ-TREE 2 was used (TIM+F+R3 model) to infer a phylogenetic tree. For the single HAdV41 genome de novo assembled, all available HAdV41 complete genomes were downloaded from GenBank aligned with MAFFT, and IQ-TREE2 was used (K2P+R2 model) to infer a phylogenetic tree.

**HLA typing**

High resolution typing for all HLA loci (HLA-A, B, C, DRB1, DRB3/4/5, DQA1, DQB1, DPA1 and DPB1) was performed using AllType™ FASTplex™ NGS Assay (One Lambda) run on an Illumina Mi-Seq platform. HLA typing was undertaken on 20 ISARIC consented patients. One patient was omitted from analysis as they were a sibling of another case. HLA types from 64 Scottish National Blood Transfusion Service apheresis platelet donors, self-identified as White British (n=15) or White Scottish (n=49) were used as control samples for comparison with patient HLA phenotype frequencies.

**Statistics**
Differences between cases and control groups were calculated using Fisher’s Exact Test for categorical variables and Mann-Whitney test for continuous variables.

HLA analysis used the Bridging ImmunoGenomic Data-Analysis Workflow Gaps (BIGDAWG) R package to derive OR and corrected p values for individual HLA alleles. Bonferroni corrected p value significance threshold, adjusted for multiple comparisons (168 HLA alleles), was $p < 3.0 \times 10^{-4}$. Significance differences between groups for other comparisons were calculated using Mann-Whitney test or t-test as appropriate.

**Data and code availability:** available on request

**Funding**

The work was funded by Public Health Scotland, the National Institute for Health Research (NIHR; award CO-CIN-01) and the Medical Research Council (MRC; grants MC UU 1201412, MC_PC_19059 & MC_PC_22004). DIAMONDS is funded by the European Union Horizon 2020 programme; grant 848196).
Acknowledgements

We wish to acknowledge the contribution of the participating children and their parents who agreed to participate in the ISARIC CCP-UK and DIAMONDS studies, and the research teams who recruited the patients. We also acknowledge the invaluable input of Eric J. Kremer from the Institut de Génétique Moléculaire de Montpellier, Université de Montpellier.

Supplementary Figures
Supplementary Figure 1: AAV2, HAdV and human herpesvirus detection by target enrichment sequencing in cases and controls. Read counts per million are plotted for HAdV (a), AAV2 (b), HHV6B (c), HSV1 (d), HSV2 (e), VZV (f), HHV6A (g), HHV7 (h), HHV8 (i) and CMV (j) in cases, healthy controls and HAdV positive children with normal =
Supplementary Figure 2: Ct values and estimated copy number for AAV2 real-time PCR. Estimated copy numbers are shown, calculated using serial dilutions of a plasmid containing the 62bp ITR product to generate a standard curve which was then used to calculate the copy number of AAV2 in samples.
Supplementary Figure 3. Reactivity to a) human seasonal coronaviruses OC229E, OC43, NL63, HKU1 and b) SARS-CoV-2 in sera from paediatric hepatitis cases. Sera from the paediatric hepatitis cases were screened for reactivity against SARS-CoV-2 nucleocapsid (N), spike (S), N-terminal domain of S (NTD) and receptor binding domain of S (RBD) by electrochemiluminescence (MSD-ECL). Reactivity of the nine samples were compared with three groups of sera from adults of known SARS-CoV-2 status; negatives (n=30), vaccinated two doses (n=28) and infected (n=39).
