Acknowledgements: Thank you to Survivor Corps for mobilizing many thousands of COVID-19 survivors to participate in research to find a cure for COVID-19, and for being the epicenter of hope for so many. We would like to express our deep gratitude to the thousands of long-haulers who spent many hours taking this survey while suffering from the impacts of PASC. The answers we need to cure PASC will come from listening and learning from those who suffer from the disease.

We would also like to thank the Precision Health Initiative at Indiana University for their support on this project.

ABSTRACT

Long-haul COVID-19, also called Post-Acute Sequelae of SARS-CoV-2 (PASC), is a new illness caused by SARS-CoV-2 infection and characterized by the persistence of symptoms. The purpose of this cross-sectional study was to identify a distinct and significant temporal pattern of PASC symptoms (symptom type and onset) among a nationwide sample of PASC survivors (n= 5,652). The sample was randomly sorted into two independent samples for exploratory (EFA) and confirmatory factor analyses (CFA). Five factors emerged from the EFA: (1) cold & flu-like symptoms, (2) change in smell and/or taste, (3) dyspnea and chest pain, (4) cognitive & visual problems, and (5) cardiac symptoms. The CFA had excellent model fit ($\chi^2 = 513.721$, $df = 207$, $p < 0.01$, TLI= 0.952, CFI= 0.964, RMSEA= 0.024). These findings demonstrate a novel symptom pattern for PASC. These findings can enable nurses in the identification of at-risk patients and facilitate early, systematic symptom management strategies for PASC.

Key words: COVID-long-haul, Symptom Clusters, Long COVID, COVID-19 pandemic, post-acute sequelae of SARS-CoV-2 (PASC)

Introduction

Long-haul COVID-19, post-acute sequelae of SARS-CoV-2 (PASC), is the persistence of symptoms that extend beyond the expected resolution of illness. PASC often causes significant disability and given the large-scale of the pandemic coupled with the lack of treatments, PASC is a global health crisis (1, 2). PASC has not yet been clinically characterized. The incidence PASC is estimated 11% to 80% (3-8) Initial COVID-19 symptom presentation varies; however, the development of PASC appears to be independent of COVID-19 symptom presentation, severity, or the presence of pre-morbid (pre-existing) health conditions (9). Persons at risk for PASC include those who were initially asymptomatic, as well as symptomatic persons independent of needing hospitalization. (4, 10, 11). PASC survivors report a variety of persistent and distressing symptoms that can last anywhere from weeks to more than a year (9). Nearly two years into the pandemic, PASC survivors continue to report symptoms and it is unclear if symptoms will eventually resolve or if a new chronic disease has emerged. We and others have enumerated and characterized PASC symptoms at the onset of illness. (4, 9, 10, 12-14). However, it is still not known how PASC symptoms evolve over time, how they temporally group or cluster, and if findings represent a statistically significant pattern.

PASC symptom presentation, and more specifically the order in which symptoms are experienced, is useful for developing and implementing self-management strategies to reduce symptom burden and improve quality of life and daily functioning. As experts in symptom science, nurse scientists are well-poised to investigate PASC symptoms and leverage the existing self-management evidence base to develop or re-tool interventions to mitigate the devastating consequences of PASC symptoms (9). Further, understanding the PASC symptom pattern allows for the exploration of the underlying biological mechanisms underpinning symptoms and their

evolution (9). Understanding symptoms and their context (i.e., biology, behaviors, etc..) is critical for the development of new interventions and pharmacological and non-pharmacological therapeutics. This study extends beyond symptom description and advances our understanding of PASC symptoms through added context, specifically symptom onset. Therefore, the aim of this study was to identify a distinct and statistically significant pattern of PASC symptoms through assessment of symptom type and symptom onset in a nationwide sample of PASC survivors (n=5,562). PASC is operationalized as experiencing symptoms more than 28 days after SARS-CoV-2 infection. In this paper, we used exploratory factor analysis (EFA) and confirmatory factor analysis (CFA). EFA was used to identify the underlying PASC symptom structure (symptom type and onset) and the temporal clustering of symptoms. CFA was used to validate findings of the EFA PASC symptom structure, and thereby yielded a distinct, statistically significant temporal pattern of symptoms among PASC survivors.

Methods

Sample and Setting

A convenience sample (n=5,562) of COVID-19 survivors were recruited (August 2020 through February 2021) through online COVID-19 survivor groups and online COVID support communities in response to a written study advertisement. Since study recruitment and data collection were completed online, the sampling frame was national. Inclusion criteria were English speaking, adults at least 18 years of age or older, and either a (self-report) positive PCR or history of healthcare provider confirmed clinical diagnosis of SARS-CoV-2 infection.

Survey and Procedures

Institutional review board (IRB) approval was obtained from Indiana University prior to recruitment and data collection. Informed consent as approved by the IRB was implied prior to the completion of the survey. Since there is no gold-standard symptom survey measure for PASC, a symptom survey was developed using unstructured social media data in which patients reported their symptoms in free text. Further details regarding survey development are reported in (Authors, in review) (14). The survey asked participants to indicate (check) symptoms they had experienced since the onset of COVID-19 and at the time of completing the survey. Participants were then asked to write in symptom onset (the number of days after SARS-CoV-2 infection that a symptom began) of symptoms they checked. A free text option was included in which participants could report any symptom not included in the survey. Symptoms reported in the free text were evaluated for consistency across participants and collapsed into common categories as appropriate. All data collection were completed electronically using REDCap.

Analytic Plan

Statistical analyses were performed using R software (Version psych 2.1.6 (EFA) and Lavaan 0.6-9 (CFA)). To ensure group equivalence descriptive statistics and measures of central tendency and *t-test* were used to describe the sample, test for differences at baseline, and onset of symptoms.

A sample of 5,562 participants were recruited, and 5,136 met criteria. The sample (n=5,136) was randomly sorted into two independent samples for EFA (n= 2,547) and CFA (n = 2589) analyses using a random number generator. The sample size exceeded the minimum criteria for subjects per item (10:1) ratio needed to conduct rigorous exploratory and confirmatory factor analyses. The following criteria were used to guide the exploratory and confirmatory factor analyses:

Exploratory Factor Analysis

Extraction and Rotation Method. A series of EFAs were performed using R to determine the factor structure of symptom onset for PASC. Latent factor structure was assessed through principal axis factoring (PAF) to extract the symptom onset for PASC factor structure. PAF accounts for the unique contribution of each item and can robustly analyze the data that violate the assumption of normality. Prior to the EFA, indicators of sampling adequacy were verified by Kaiser-Meyer-Olkin (KMO) and Bartlett's Test of Sphericity (15).

Determination of Factors and Item Reduction. The scree plot and eigenvalue values for each factor guided the evaluation to determine the most parsimonious factor structure. Criteria reported by Costello and Osborne were used for interpretation of the scree plot (15). Kaiser criterion, which recommends an eigenvalue ≥ 1 , was used for factor retention and the assessment of eigenvalues (16). The interpretation of the scree plot and eigenvalue of each factor determined the number of factors captured by the symptom onset of PASC.

Item Retention and Removal Criteria. *A priori* criteria for item retention were had primary factor loadings ≥ 0.40 , secondary factor loadings < 0.30 , and did not have primary factor loadings on more than one factor (17). Items not meeting these criteria were removed individually. The EFA was repeated until all retained items met these criteria.

Labeling of Factors and Internal Reliability Consistency. The parsimonious factor structure was derived from the EFA and then labeled based content of the items retained. Evaluation of the internal reliability consistency of each factor was performed to assess the contribution of each item to the factor or total score of the symptom onset for PASC.

Confirmatory Factor Analysis

Determination of Model Fit. The symptom onset for PASC model identified by the EFA was evaluated for validity using a first-order CFA. We used the following goodness-of-fit indices to determine model fit: χ^2 , Tucker Lewis Index (LTI: >0.90 acceptable, >0.95 excellent), the Comparative Fit Index (CFA: >0.90 acceptable, >0.95 excellent), and the Root Mean Square Error of Approximation (RMSEA: <0.08 acceptable, <0.05 excellent) (18). Paths between error terms were added to enhance the goodness-to-fit of these data to the model based on interpretation of the above modification indices (19).

Results

Sample Characteristics

Sample demographics are provided in Table 1. No differences were observed between the EFA, and CFA independent samples based on sex, race/ethnicity, and age. The average time from SARS-CoV-2 infection to completing the questionnaire was 105.2 days (SD 58).

Exploratory Factor Analysis to Identify Underlying Factor Structure

The first independent sample of 2,547 PASC survivors was used for EFA. In the EFA, the most parsimonious structure included five factors with a variable number of items per factor (range 3-10). See Table 2 for factor loadings. The mean onset of each symptom and its corresponding factor are presented in Figure 1. Based on the content of the items retained on each factor and the magnitude of these items' factor loading, each factor was labeled as follows: Cold & flu-like symptoms (Factor 1), Change in Smell and/or taste (Factor 2), Dyspnea & chest pain (Factor 3), Cognitive-visual symptoms (Factor 4), and Cardiac symptoms (Factor 5). For each factor the item-to-total correlations (range 0.50-0.95) and inter-item correlations (range (0.23-0.92)) are provided in Table 3. See Figure 2 for the EFA model.

Confirmatory Factor Analysis Confirms Pattern of Symptom Onset

A five-factor structure was examined for validity with the second independent sample of 2,589 PASC survivors. Table 4 provides the goodness-of-fit for the 5-factor structure from the EFA. The initial model is the 5-factor model with all items retained from the EFA. A stepwise approach was then taken whereby paths from the stated items error terms were added sequentially. The final structure model was the best fitting model ($\chi^2 = 513.721$, $df = 207$, $p < 0.01$, $TLI = 0.952$, $CFI = 0.964$, $RMSEA = 0.024$) and the final model is shown in Figure 3.

Discussion

To our knowledge this study is one of the first nationwide studies conducted among PASC survivors to document a distinct and significant pattern of symptoms (symptom type and onset) among non-hospitalized persons with confirmed SARS-CoV-2 infection. Findings from this study warrant additional discussion and context to better understand their nursing implications.

We and others have described and characterized a broad range of symptoms associated with SARS-CoV-2 infection, as well as symptoms that persist for months and are a hallmark feature of PASC (3, 4, 9, 10, 13, 20). A limitation shared among many published studies is the use of checklists derived from clinician experience in managing COVID-19. Our initial understanding of symptoms associated with COVID-19 arose from our understanding that SARS-CoV-2 predominantly affected the respiratory system which limited initial symptom data. The depth and breadth of symptoms experienced among PASC survivors is just emerging. Indeed, an international study showed PASC survivors experience over 55 symptoms (13). Moreover, in our own work (3, 9), findings at illness presentation associated with the

development of PASC is more extensive than the initial hallmark symptoms of SARS-CoV-2 infection, especially as asymptomatic persons are also at risk.

This study provides new information that points to a distinct and statistically significant pattern of PASC symptoms based on symptom type and symptom onset originally derived from unstructured patient reports. Additionally, this study adds to the science by providing a more granular assessment of PASC symptoms, early post-infection, than is has been measured other longitudinal work that commonly report within set timeframes (e.g., 4-week intervals). Our findings suggests that the evolution of PASC symptoms may follow a predictable pattern inclusive of a long duration (M days post-infection=105 days). This observation is troubling as it suggests that for some the sequelae of SARS-CoV-2 infection are ongoing and may be life-long. Further, this protracted length of illness suggests a major public health crisis is emerging and is affecting previously healthy and those with pre-morbid conditions alike. Finally, developing and implementing preventative interventions hinges upon understanding the course of the disease in the absence of any intervention. Given that PASC has no treatments or cure, this study documents the temporal order of symptoms during the evolution of the disease, in the absence of intervention, and provides the foundation for preventative and self-management strategies for PASC symptoms.

The confirmed factors (cold & flu like symptoms, change in smell and taste, dyspnea & chest pain, cognitive & visual symptoms, and cardiac symptoms) follow an arguably sequential pattern that could accompany progressive or persistent inflammation accompanied by endothelial activation. Other studies report elevated concentrations of a variety of cytokines (i.e., IL-6, and others) as well as persistent activation of immune cells for many weeks after SARS-CoV-2

infection (21-24). However, few studies have used biomarkers to correlate biological processes with symptom trajectories. This is an area ripe for exploration among nurse researchers.

A strength of this study is that it included mostly women aged 30-59 who identified as White. This is advantageous solely for conducting EFA and CFA because limiting sample collection from a wide range of populations is recommended to minimize the chance that factors present in one population will be obscured when pooled together with other populations. While this may limit the generalizability of the findings, it is nonetheless important because prior research has demonstrated that PASC affects women to a greater extent than men (3, 25) Further, this research serves as a basis for future comparisons between sex, races, ethnicities, and age groups to guide further research. This study asked PASC survivors to recall symptom type and their onset which is subject to recall bias unless symptoms were recorded via diary or tracking in real time by PASC survivors. However, viewing this weakness should be balanced with weaknesses of other methods of data collection such as clinician recorded symptoms (e.g. in the electronic health record) which has been shown to be discordant with patient reports (26, 27). Ideally future work should be prospective and leverage multiple data sources in real time including patient report and triangulating data sources (e.g., wearable devices, patient report, clinical diagnostics, etc....) that have been used in other studies. Additionally, prospective cohort data studies are particularly difficult to establish an emerging pandemic as pertinent constructs may not be known.

Second, the survey was conducted among individuals with symptoms following SARS-CoV-2 infection, thus excluding those who were asymptomatic. Moreover, most participants did not require hospitalization and/or supplemental oxygen delivery and would be considered to have mild-COVID-19. Most research in this area has been among hospitalized patients with COVID-

19, limiting generalizability to those with less severe or asymptomatic initial presentation. (7, 10, 28). However, these data should not suggest that persons with asymptomatic infection do not develop PASC. Multiple studies suggest that those with asymptomatic SARS-CoV-2 infection are also at risk for long-term sequelae from COVID-19, although the incidence is unclear. In our work and others, data suggest that persons with PASC likely experience an evolution of symptoms that is unique from persons who do not develop PASC despite SARS-CoV-2 infection (3, 9, 28) Model validation utilizing a large sample of patients with SARS-CoV-2 who report prompt resolution of symptoms should be used to validate and understand if, and, or when a bifurcation in symptoms happens.

Third, this survey was conducted earlier in the COVID-19 pandemic when the alpha variant was dominant. Because the delta variant is far more contagious and symptom presentation differs slightly (29), it is unclear if the pattern reported here would be consistent between the two variants. This is an ongoing and active area of research for our team. Also, breakthrough infections are occurring among vaccinated persons, and data suggest that vaccinated individuals are less likely to develop PASC following SARS-CoV-2 infection. However, additional studies are needed to assess PASC among the vaccinated, and should a new variant arise that minimizes the efficacy of current vaccines, the effect of breakthrough infections in the development of PASC would need to be re-evaluated.

Finally, there are potential implications for research and clinical practice (30). Nursing has an established history in symptom science and our collective expertise is needed at this time to address an unprecedented global health crisis. In addition to advancing the biological and molecular underpinnings of symptoms, Nursing is poised to rapidly re-tool and repurpose symptom management interventions to address symptoms among individuals with PASC. As the

science develops around PASC, it may be possible to implement pharmacological and non-pharmacological interventions early during SARS-CoV-2 infection to mitigate potential long-term sequelae. An effective response to this global health crisis will require clinical and research collaboration among nurses to address the symptom burden afflicting the millions and rising numbers of individuals with PASC.

Conclusion

PASC is a global health crisis that has emerged in response to the novel coronavirus, SARS-CoV-2. This study describes a distinct and statistically significant symptom pattern associated with PASC. We hope that this study will serve as a foundation upon which future studies can further characterize and understand PASC. As the pandemic continues, similar studies are needed to validate our findings and advance the understanding of PASC.
