Internal and external forces affecting vaccination coverage: modeling the interactions between

vaccine hesitancy, accessibility, and mandates

Kerri-Ann Anderson and Nicole Creanza

Department of Biological Sciences and Evolutionary Studies Initiative, Vanderbilt University,

Nashville, TN 37212

Abstract:

Society, culture, and individual motivations affect human decisions regarding their health

behaviors and preventative care, and health-related perceptions and behaviors can change at the

population level as cultures evolve. An increase in vaccine hesitancy, an individual mindset

informed within a cultural context, has resulted in a decrease in vaccination coverage and an

increase in vaccine-preventable disease (VPD) outbreaks, particularly in developed countries

where vaccination rates are generally high. Understanding local vaccine cultures, which evolve

through an interaction between beliefs and behaviors and are influenced by the broader cultural

landscape, is critical to fostering public health. Vaccine mandates and vaccine inaccessibility are

two external forces that interact with individual beliefs to affect vaccine-related behaviors. To

better understand the population dynamics of vaccine hesitancy, it is important to study how

these external factors could shape individual vaccination decisions and affect the broader health

culture. Using a mathematical model of cultural evolution, we explore the effects of vaccine

mandates and vaccine inaccessibility on a population's level of vaccine hesitancy and vaccination

behavior. We show that vaccine mandates can lead to a phenomenon in which high vaccine

hesitancy co-occurs with high vaccination coverage, and that high vaccine confidence can be

maintained even in areas where access to vaccines is limited.

Introduction:

A comprehensive understanding of health behaviors and their potential for exacerbating or mitigating disease risk requires insight into how cultural beliefs influence these behaviors. Local vaccine cultures—the shared beliefs among individuals within a community about vaccine preventable disease etiology, prevention, and treatment—can affect an individual's vaccine attitudes and decisions [1]. The definition of "vaccine hesitancy" varies between sources, spanning from an attitude of uncertainty about vaccines to the behavior of vaccine refusal. Here we use the definition from [2]: "a state of indecision and uncertainty that precedes a decision to become (or not become) vaccinated." Vaccine hesitancy was recently named one of the World Health Organization's ten threats to global health [3] because of its link to reduced vaccination coverage and more frequent outbreaks of vaccine-preventable diseases (VPDs) worldwide. Vaccine hesitancy is a key indicator of the vaccine culture of a population, which is influenced by multiple societal- and individual-level factors, such as the vaccination coverage of the population, the perceived risk of vaccine-preventable diseases, the level of trust in specific vaccines, and the confidence in the healthcare system [4,5].

Two non-cultural factors that play a role in shaping vaccine cultures are vaccine mandates, which drive vaccination uptake (even among vaccine-hesitant people), and vaccine inaccessibility, which hinders vaccine uptake (even among vaccine-confident people). More is understood about the effects of mandates. Compulsory vaccination has been met with opposition since its implementation in the 1800's [6,7]. This opposition, intertwined with religious and political ideas, led to the allowance of vaccination exemptions based on medical and non-medical (e.g. religious or philosophical) reasons [8]. Though the implementation of compulsory vaccinations generally results in a drastic reduction in disease incidence and mortality [9,10], the high vaccination coverage that follows can facilitate the public perception of reduced disease severity and thus reduced vaccine necessity [11,12]. In this vein, non-medical exemptions to compulsory vaccinations have been increasing, particularly in wealthier countries where belief systems can act as the main barrier to vaccination, as opposed to lack of vaccine access [13,14]. This rise in non-medical exemptions appears to have a non-trivial effect on public health, since these exemptions are correlated with the recent increase in VPD outbreaks [15,16]. However, the circumstances under which vaccine mandates might lead to increased vaccine hesitancy remain uncertain.

Even less understood is the potential association between vaccine (in)accessibility and

vaccine attitudes. Vaccine accessibility issues are external pressures that negatively impact

vaccination rates and coverage. Challenges to vaccine accessibility are particularly prevalent in

low and middle-income countries as well as rural areas in developed countries [17,18]. For

example, storage capabilities, distribution logistics, and affordability can limit the number of

vaccine doses available in a specific area, and thus reduce the number of individuals who can

receive a vaccine, leaving vulnerable communities at risk for a VPD outbreaks [17,19]. This limited

access may also interact with psychological and cultural factors, such as distrust in the healthcare

system, potentially exacerbating the effects of low vaccine accessibility. Further, vaccine cultures

can be shaped by experience with vaccines and the disease: for example, living in a rural area

could limit exposure to the disease and alter the perception of disease risk, and a lack of vaccine

access for an extended period could entrench certain attitudes about vaccines in a culture. Thus,

to explain the differences in vaccination outcomes and resulting disease risk across human

populations, it is crucial to better understand how cultural beliefs and behaviors interact with

external pressures that increase or reduce vaccination coverage.

Cultural niche construction is a process in which humans modify their cultural

environments—for example, their beliefs, behaviors, preferences, and social contacts—in ways

that subsequently alter evolutionary pressures on the population and its culture [20].

Mathematical models of cultural niche construction have been used to explain the evolution of

behaviors related to religion, fertility, and large-scale human conflict [20–25]. Since health

cultures can be shaped by or influence the larger cultural landscape, the cultural niche

construction framing can give insight into the cultural dynamics shaping disease risk. By using this

type of model to simulate the interactions between beliefs and behaviors, we seek to understand

how vaccine cultures affect vaccination coverage, as well as how vaccine-related beliefs and

behaviors are affected by external forces, such as the availability of vaccines and the degree to

which they are compulsory.

We adapted a cultural niche construction framework to model vaccination beliefs and

behaviors, incorporating the transmission of vaccine culture both from parents and from the

community [26]. Using this model, we previously demonstrated that the overarching cultural

landscape, including the likelihood of adopting vaccine hesitancy and the probability of

transmitting it to one's children, determines the equilibrium levels of vaccination coverage and

vaccine hesitancy in a population. In addition, we demonstrated that the transmission of vaccine

confidence and positive vaccine perception are imperative to maintaining high levels of

vaccination coverage, especially when individuals preferentially choose a partner with shared

vaccine beliefs. In this manuscript, we expand the scope of this model to explore how the

vaccination coverage and vaccine hesitancy in a population could be affected by external forces.

In particular, we focus on vaccine mandates and vaccine inaccessibility, which both lead to a

disconnect between parental vaccine beliefs and their vaccination behaviors, but in different

directions: vaccine mandates can increase the chances that vaccine-hesitant parents will

vaccinate their children, and vaccine inaccessibility can decrease the chances that vaccine-

confident parents will vaccinate their children. We explore the effects of these external forces on

the dynamics of both vaccine beliefs and vaccination coverage, providing insight into the

differences between cultural development in the opposing contexts of mandates and

inaccessibility.

Methods:

We build on a more general cultural niche construction framework of [24,26] to assess the

effects of vaccine mandates and vaccine accessibility on the resulting landscape of vaccination

coverage and vaccine confidence. For a population of individuals, we track the status of

vaccination coverage and vaccine confidence over time; within this population, individuals mate,

decide whether to vaccinate their offspring, and transmit a vaccine attitude trait. Their decision

to vaccinate is influenced by their own beliefs and their vaccination states, and population trait

frequencies are further modulated by vaccination frequency dependent cultural selection

pressures.

Each individual in our model (depicted in **Figure 1**) has a vaccination (**V**) trait, either V^+

(vaccinated) or V^- (unvaccinated), and an attitude (A) trait, either A^+ (vaccine confident) or A^-

(vaccine hesitant), resulting in four possible phenotypes (V^+A^+, V^+A^-, V^-A^+, and V^-A^-) that we

initialize with frequencies structured to represent those of the United States: V^+A^+ (i.e. frequency

of vaccinated, vaccine confident individuals) = 0.81, $V^+A^- = 0.1$, $V^-A^+ = 0.07$, $V^-A^- = 0.02$. These

frequencies were estimated using reports of Measles-Mumps-Rubella vaccination rates and

estimates of vaccine attitude frequencies obtained from various sources in the literature [27,28].

In each iteration, individuals mate randomly within the population. Each parental pair vaccinates

their offspring with probability $B_{m,n}$ (i.e., vertical transmission of vaccination); in general, this

probability increases with each vaccinated and vaccine-confident parent. This vaccination

probability is influenced by two factors: whether each of the parents are themselves vaccinated

(b_m), and whether each of the parents are vaccine confident or hesitant (c_n). The probability that a

couple vaccinates their offspring is calculated as $B_{m,n} = c_n \left(\frac{1+b_m}{2} \right)$, to account for the influence

of both vaccination states and vaccine attitudes (see **Table 1** and **Table S1** for an explanation of

the m and n subscript assignments). We implement vaccine mandates and inaccessibility by

modulating the influence that parental vaccine attitudes have on the likelihood that they

vaccinate their offspring (by increasing or decreasing c_n): for example, a vaccine mandate will

make a vaccine-hesitant parent more likely to vaccinate their child, and vaccine inaccessibility will

make a vaccine-confident parent less likely to vaccinate their child.

Each parental pair also transmits a vaccine attitude trait to their offspring (i.e., vertical

transmission of beliefs) with vaccine confidence transmitted at probability C_n and vaccine

hesitancy at probability $1-C_n$. We set the probability of transmitting vaccine confidence to be

highest for two vaccine-confident parents and lowest for two vaccine-hesitant parents (**Table 1**).

Next, cultural selection (σ) operates on the resulting phenotype frequencies such that the

frequency of vaccination in the population is greater or less than expected given the predicted

probabilities that vaccine-confident and -hesitant parents vaccinate their offspring. The

proportion of vaccinated individuals in the population is multiplied by 1+σ, such that a positive σ

increases the proportion of vaccinated individuals and a negative σ decreases it. This process

encompasses the various factors that might make parents more or less likely to vaccinate,

including the severity of the disease and the general trust in the healthcare system. Since the

perceived benefit of the vaccine might vary based on the vaccination coverage in the population,

we allow σ to depend on the frequency of the V^+ trait: when the frequency of vaccination is low,

the effects of the disease are more evident and individuals are more likely to vaccinate (high σ),

but when the frequency of vaccination is high, the risks of the disease are masked and individuals

are less likely to vaccinate (lower σ). The equation relating the frequency of V^+ and σ is given in

the **(Figure S1)**.

Finally, oblique interactions (cultural influences from non-parental individuals) then act

to further modify trait frequencies in the population. Individuals in the simulation can change

their vaccine attitudes based on interactions with others and their perceptions of their

surroundings. If the vaccination coverage in the population is low, we consider the negative

effects of the disease to be more apparent and thus people will be less likely to adopt a vaccine-

hesitant attitude, and if the vaccination coverage is high, the negative effects of the disease are

prevented (amplifying the perception of the vaccine's risks and costs, however small) and people
might be more likely to become vaccine hesitant (**Figure S2**). Each subsequent iteration of the
model begins with the phenotype frequencies produced at the end of the current iteration. The
simulation is run until phenotype frequencies reach equilibrium (**Figure 1, Table 1**). For more
detail see **Supplemental Text S1** and [26]. All code to run the simulations is provided at
www.github.com/CreanzaLab/VaccineModel.

Figure 1. Workflow of a single iteration of the model: The schematic shows the processes within a single
model iteration. The model is initialized with the phenotypic frequencies (V^+A^+, V^+A^-, V^-A^+, V^-A^-) in the
population. After individuals mate and reproduce, they vertically transmit vaccination and attitude traits
to their offspring. Vaccination trait frequencies are further modulated by cultural selection. Oblique
transmission (cultural transmission from non-parental adults in the population) follows, which may lead
offspring to alter their attitude state. (Parameters, their definitions, and default values are listed in **Table
1.**)
168

169 **Table 1: List of parameters, their definitions, and baseline values.**

Parameter	Meaning	Parameter	Meaning
V	Vaccination state (V^+ vaccinated, V^- unvaccinated)	A	Vaccine attitude (A^+ confident, A^- hesitant)
$B_{m,n}$	Probability that parental pairs vaccinate their children, which depends upon the parents' vaccination states (b_m) and vaccine attitudes (c_n) (given in **Table S2**)	C_n	Probability that parental pairs transmit vaccine confidence to their children **Baseline:** C_0 = 0.01, C_1 = C_2 = 0.5, C_3 = 0.99
b_m	Probability that parental pairs	c_n	Probability that parental pairs

	support offspring vaccination given their vaccination states __Baseline: b_0= 0.01, b_1= b_2 = 0.5, b_3 = 0.99__		support offspring vaccination given their vaccine attitude __Baseline: c_0= 0.01, c_1= c_2 = 0.5, c_3 = 0.99__
σ	Comprehensive selection coefficient for V^+, dependent on the population-wide vaccination rate (see **Figure S1**)	σ_{max}	The highest additional benefit that can be conferred by vaccination __Baseline: σ_{max}= 0.1__
Parameter subscripts indicating traits of the mating pair (m and n in b_m, c_n, C_n, and $B_{m,n}$)		$V^-×V^-$: m=0; $V^-×V^+$: m=1; $V^+×V^-$: m=2; $V^+×V^+$: m=3 $A^-×A^-$: n=0; $A^-×A^+$: n=1; $A^+×A^-$: n=2; $A^+×A^+$: n=3	

Results:

Compulsory Vaccination and Vaccine Inaccessibility

We hypothesize that parental vaccine attitudes influence their use of exemptions and thus levels of non-vaccination will differ based on parental attitudes under a mandated vaccination system. Therefore, we simulate the effects of compulsory vaccination by modulating the influence of a couple's vaccine attitudes on their likelihood of vaccinating their offspring (c_n); in other words, a vaccine mandate alters the influence of a couple's vaccine attitude on their decision to vaccinate. We assume the implementation of mandates would increase vaccination in couples with at least one vaccine-hesitant individual. If vaccination exemptions are permitted, we expect that $A^- × A^-$ couples (those with two vaccine-hesitant individuals) would be most likely to obtain exemptions, followed by mixed attitude ($A^- × A^+$ or $A^+ × A^-$) couples, with vaccine confident couples ($A^+ × A^+$) being least likely. Hence, to model the effects of implementing a lenient mandate, we increase attitude influence parameters from baseline values (**Table 1**) to c_0 = 0.3, c_1 = c_2 = 0.7, c_3 = 0.99. Assuming mixed attitude ($A^- × A^+$ or $A^+ × A^-$) couples exhibit the most variability in their likelihood of transmitting vaccine confidence, we then examined the effect of the interaction between the maximum cultural selection coefficient (σ_{max}) and mixed-attitude confidence transmission probability ($C_1=C_2$) (**Figure 2**).

Modeling the effects of a vaccine mandate reveals a decoupling of vaccination coverage and vaccine confidence when parents are more likely to transmit vaccine hesitancy (**Figure 2C-D**). Even when vaccine confidence is very low (specifically at mixed-trait couple confidence transmission probabilities below 0.5; red region in **Figure 2D**), vaccination coverage is much higher than without the mandate (compare **Figure 2C-D** to **Figure 2A-B**). This suggests that an

external pressure to vaccinate is able to overcome the opposing cultural pressure imposed by

hesitancy in the population.

Figure 2: External factors (vaccine mandates and vaccine scarcity) disconnect levels of vaccine confidence from vaccination coverage. Heatmaps showing equilibrium vaccine coverage and vaccine confidence levels with an accessible vaccine and no mandate (**A, B**), with an accessible vaccine and a lenient mandate (**C, D**) and an environment with vaccines somewhat inaccessible (**E,F**). Assuming mixed-attitude couples might have the most variability in their likelihood of transmitting vaccine confidence to their offspring, we vary $C_1 = C_2$ on the vertical axis), and maximum selection coefficient (σ_{max}) on the; horizontal axis. A lenient mandate (**C, D**) is modeled by $c_0 = 0.3$, $c_1 = c_2 = 0.7$, $c_3 = 0.99$; vaccine inaccessibility (**E, F**) is modeled by $c_0 = 0.01$, $c_1 = c_2 = 0.3$, $c_3 = 0.7$. Unspecified parameters are given in **Table 1**. These simulations show an inverse correlation between vaccination coverage and vaccine confidence at $C_n < 0.5$ under a strict mandate, and $C_n > 0.5$ when vaccine access is limited. Baseline conditions (**Table 1**) are highlighted by black boxes in each heatmap.

Figure 3: Vaccine mandates and inaccessibility drive different distributions of both vaccination coverage and vaccine confidence. Phenotype and trait frequencies are plotted over 100 model iterations. Compared to baseline transmission levels (panel **A**, parameter values given in **Table 1**), a lenient vaccine mandate (c_0 = 0.3, c_1 = c_2 = 0.7, c_3 = 0.99; panel **B**) leads to increased vaccination coverage at equilibrium (black line) but decreased vaccine confidence levels (magenta line). In contrast, when a vaccine is somewhat difficult to access (c_0 = 0.01 ; c_1 = c_2 = 0.3 , and c_3 = 0.7; panel **C**), vaccination coverage is lower than in panel **A** but vaccine confidence is higher. The specific simulations shown here are highlighted with black rectangles on the heatmaps in **Figure 2**.

Table 2: Change from Baseline Equilibrium Frequencies. Final equilibrium frequencies for baseline, a lenient vaccine mandate, and a somewhat inaccessible vaccine are shown along with the percent difference from baseline frequencies. Colored lines in the first row correspond to the line colors in **Figure 3**. Negative changes are indicated by a red downward pointing triangle; positive changes are indicated by green upward pointing triangle. A vaccine mandate leads to increased vaccination among vaccine-hesitant individuals, and vaccine inaccessibility leads to decreased vaccination and increased vaccine confidence among unvaccinated individuals.

Phenotype		V^+A^+ ▬	V^+A^- ▬	V^-A^+ ▬	V^-A^- ▬	V^+ ▬	A^+ ▬
Baseline Equilibrium Frequencies		**0.4634**	0.0966	0.2	**0.2399**	**0.5601**	0.6634
Percent Diff. from Baseline	**Mandate**	**0.4217** (- 9%) ▼	0.1911 (98%) ▲	0.1458 (-27%) ▼	**0.2413** (1%) ▲	**0.6129** (9%) ▲	0.5675 (-14%) ▼
	Inaccessibility	**0.3443** (-26%) ▼	0.0433 (-55%) ▼	**0.4116** (106%) ▲	0.2007 (-16%) ▼	0.3877 (-31%) ▼	**0.7560** (14%) ▲

Next we compared the results of our model of a lenient mandate to those of a somewhat

inaccessible vaccine (**Figure 2E-F**). To represent this scenario, we reduced the influence of

parental vaccine attitudes on vaccination behaviors for couples with at least one confident

individual (i.e. reducing c_1, c_2, c_3 from default values). In this simple representation of a vaccine-

scarce environment, we assume that parents' confidence in vaccines would have reduced

influence on their ability to vaccinate their offspring, that is, their vaccine confidence does not

ensure their ability to overcome vaccine inaccessibility. Hesitant couples are least likely to

vaccinate their offspring regardless of vaccine availability, but couples who would likely vaccinate

their offspring given the chance would have difficulty doing so due to the lack of access. Attitude

influence parameters were set to $c_0 = 0.01$; $c_1 = c_2 = 0.3$, and $c_3 = 0.5$, and as before, we

modulated the maximum cultural selection coefficient of vaccination (σ_{max}) and confidence

transmission (C_1 and C_2) (**Figure 2E-F**). Vaccination coverage was noticeably reduced overall,

while vaccine confidence increased slightly across the parameter space. Juxtaposed with the

mandate scenario (**Figure 2C-D**), our vaccine scarcity models produce an opposite deviation of

vaccination coverage from vaccine confidence levels: when vaccines are mandated, we observe

increased vaccination coverage in low-confidence environments, and when vaccines are

inaccessible, we observe lower than expected vaccination coverage (<50%) in a predominantly

vaccine-confident environment (>90%) (**Figure 2**).

In the three scenarios examined thus far—baseline (no mandate and accessible vaccines),

a lenient mandate, and somewhat inaccessible vaccines)—most of the variability in equilibrium

frequencies across the parameter space occurs at confidence transmission levels between $C_1 = C_2$

$= 0.4 - 0.6$ (**Figure 2**). This threshold region separates definitively higher and definitively lower

vaccination coverage and vaccine confidence outcomes. There is also a noticeable effect of actual

and perceived vaccine fitness (σ_{max}) in this region of the heatmap: as cultural selection for

vaccination increases at any fixed probability of confidence transmission, vaccination coverage

and vaccine confidence levels at equilibrium are increased. Changes in vaccination and

confidence frequencies are not independent of each other, as these effects are the consequence

of changes in phenotypic frequencies. Therefore, for each scenario, we plotted the temporal

dynamics of each phenotype (**VA**) and the vaccination (V^+) and confidence (A^+) traits at baseline

parameter values (**Figure 3**), then calculated the difference in frequency from baseline

equilibrium (**Table 2**). With an accessible vaccine that is not mandated (**Figure 3A, Table 2**), the

phenotype frequencies of the system equilibrate generally with either vaccinated and vaccine

confident (V^+A^+) or unvaccinated and vaccine hesitant (V^-A^-) individuals most abundant (**Figure**

3A, Table 2). Though these two phenotypes remain the most abundant when a lenient vaccine

mandate is implemented, the equilibrium frequency of vaccinated but vaccine-hesitant

individuals (V^+A^-) is greatly increased compared to baseline (**Figure 3B**, **Table 2**). Interestingly, a

mandate also results in a higher frequency of unvaccinated and vaccine-hesitant individuals (V^-A^-

), while reducing vaccinated and vaccine-confident individuals (V^+A^+) in the population. Vaccine

inaccessibility, on the other hand, resulted in approximately double the frequency of

unvaccinated but vaccine-hesitant (V^-A^+) individuals. In summary, compared to baseline

outcomes, implementation of a mandate increases vaccination coverage at the expense of

confidence by driving vaccination in hesitant individuals, and vaccine inaccessibility promotes

confidence despite low vaccination coverage by driving confidence in unvaccinated individuals.

We next examined the effects of varying all of the vaccine confidence parameters in

concert (C_0, C_1 C_2 and C_3), instead of focusing on the vaccine confidence transmission of mixed-

attitude couples. We varied all C_n parameters simultaneously within a specified range of values

(**Table S3**) across various levels of mandate strictness (**Figure 4**) and vaccine inaccessibility (**Figure

5**). As before, we varied these parameters in conjunction with the maximum cultural selection

coefficient σ_{max}. The clear disjunction between higher and lower vaccination (V^+) and vaccine

confidence (A^+) frequencies observed in **Figure 2** is not observed when the probability of

confidence transmission is modulated for all couples. When mixed-attitude couples transmit

confidence to their offspring at high ($C_1 = C_2 > 0.5$) or low ($C_1 = C_2 < 0.4$) probabilities, which skews

population attitude frequencies to either highly confident or highly hesitant, the subsequent

offspring are more likely to vaccinate (in a confident population) or not vaccinate (in a hesitant

population) (**Figure 2**). Similarly, if all couple types are transmitting confidence at lower

probabilities or higher probabilities (i.e. C_0, C_1, C_2, and C_3 are all lower or higher, respectively),

vaccination frequencies will equilibrate at either lower levels or higher levels (**Figure 4A**).

However, if all couples are transmitting confidence at mid-range probabilities (or C_1 and C_2 are

closer to 0.5), the population equilibrates at more polymorphic frequencies, that is, both forms of

each trait coexist in the population at moderate frequencies.

Equilibrium vaccination coverage increases as cultural selection for vaccination increases

in both mandated vaccines (**Figure 4C, E**) and vaccine inaccessibility scenarios (**Figure 5C, E**);

confidence frequencies remain more consistent across the range of cultural selection pressures

(**Figure 4D, F, Figure 5D, F**). When we model an increase in vaccine mandate strictness (increased

difficulty in obtaining exemptions), vaccination frequencies are increased (**Figure 4C, E**). On the

other hand, greater degrees of inaccessibility lead to larger reductions in vaccination coverage
(**Figure 5C, E**), and lower coverage occurs despite higher levels of vaccine confidence
300

Figure 4: Increasing mandate strictness and increased cultural selection drive vaccination coverage .
Heatmaps showing final vaccination coverage (**A, C, E**) and corresponding vaccine confidence (**B, D, F**)
after 100 time-steps while simultaneously varying all confidence transmission probabilities (C_n; vertical
axis) and maximum selection coefficient (σ_{max}; horizontal axis). We show an accessible vaccine and no
mandate (c_0= 0.01, c_1= c_2 = 0.5, c_3 = 0.99) (**A, B**), an accessible vaccine and a lenient mandate (c_0 = 0.3, c_1 =
c_2 = 0.7, c_3 = 0.99) (**C, D**) and a strict mandate (c_0 = 0.5, c_1 = c_2 = 0.9, c_3 = 0.99) (**E,F**). C_n values are set within
the range indicated on the vertical axis with C_0 taking the lowest value and C_3 taking the highest value
(**Table S3**).

Figure 5: Vaccine inaccessibility reduces vaccination coverage despite high levels of vaccine confidence. Heatmaps showing final vaccination coverage (**A, C, E**) and corresponding vaccine confidence (**B, D, F**) after 100 time-steps while simultaneously varying all confidence transmission probabilities (C_n; vertical axis) and maximum selection coefficient (σ_{max}; horizontal axis). C_n values are set within the range indicated on the vertical axis with C_0 taking the lowest value and C_3 taking the highest value (**Table S3**). We simulate an accessible vaccine and no mandate ($c_0 = 0.01$, $c_1 = c_2 = 0.5$, $c_3 = 0.99$) (**A, B**), a somewhat inaccessible vaccine ($c_0 = 0.01$; $c_1 = c_2 = 0.3$, and $c_3 = 0.7$) (**C, D**) and an inaccessible vaccine ($c_0 = 0.01$, $c_1 = c_2 = 0.1$, $c_3 = 0.5$) (**E,F**).

Discussion:

Here, we build on the cultural niche construction framework proposed by [26] to model the cultural spread of vaccine attitudes and vaccination behavior in the presence of external forces imposed by two scenarios: vaccine mandates and vaccine inaccessibility. Multiple factors influence an individual's vaccine-related beliefs and a couple's decision to vaccinate their offspring, including their own vaccination status and their perception of the relative risks of the disease and the vaccine. As such, it is important that we understand how public health policies, such as vaccine mandates and barriers to vaccination, such as geography or affordability, can

shape vaccine cultures and thus affect public health. Using a cultural niche construction approach

allows us to explore the effects of the interplay between external forces and cultural factors

providing further insight into how vaccine cultures are formed, maintained, and evolve.

With our initial model [26], we showed that when population traits are at or near an

equilibrium, we can infer that a population with high vaccination coverage will have low rates of

vaccine hesitancy and vice versa. However, when there are external pressures as modeled here,

such as increased pressure to vaccinate or difficulty in acquiring vaccination exemptions, an

undercurrent of vaccine hesitancy can persist in a relatively well-vaccinated population,

potentially limiting the adoption of newly introduced vaccines. This possibly contributes to the

unexpected lag in uptake of newer vaccines, such as the COVID or HPV vaccines, in communities

with otherwise high vaccination rates [29–31]. The perceived increase in hesitancy surrounding

new vaccines may actually be existing vaccine hesitancy becoming apparent. In addition, "fence

sitters", those who have not made a firm stance regarding vaccines and thus could be more

influenced by targeted campaigns [28], may develop higher levels of uncertainty about new

vaccines than their parents had about existing ones.

In contrast to the effect of vaccine mandates, by modeling vaccine inaccessibility we

illustrate another important pattern: reduced vaccination coverage in a vaccine confident culture.

In a vaccine-scarce environment, an individual's attitude regarding vaccines has less influence on

vaccination behavior due to the barrier imposed by resource availability. As a result, a population

may be undervaccinated despite holding vaccine-affirming beliefs. In addition, a health culture

previously shaped by vaccine inaccessibility could potentially ingrain specific behavioral practices

(for example, visiting the doctor only when a child is sick and not for a regular vaccine schedule)

that are not easily modified even if vaccines become more readily available. These vaccine

scarcity scenarios are most likely to exist in low- and middle-income countries in which vaccine

acquisition, storage and/or distribution resources are insufficient [32–34] whereas the opposite

scenario (low vaccine confidence–high vaccination coverage) after vaccine mandates is most

common in developed nations [35]. In summary, we find that vaccine mandates can result in high

vaccination coverage even in a culture of hesitancy, and that lack of access to vaccines can

produce the inverse: low vaccination coverage in a culture of confidence.

It is difficult, as with any system, to fully capture the complex reality of vaccine hesitancy

and vaccination behavior with a mathematical model. Caveats of this model include the lack of

empirical data to inform how we model the influence of vaccine confidence on vaccination

behaviors in the face of mandates or vaccine inaccessibility. In addition, our model simplifies the

process of human population turnover with discrete generations; in reality, of course, population

turnover is asynchronous and multiple generations can have cultural interactions with one

another [26]. However, this simple model is able to demonstrate interesting scenarios that

confirm the importance of understanding the culture of the communities in which public health

policies act, and how the cultural landscape might affect specific outcomes. A community is most

protected from VPD outbreaks if two conditions are met: vaccination coverage achieves or

exceeds herd immunity levels, and future vaccinations are not threatened by underlying vaccine

hesitancy. Since increasing vaccination coverage might require different strategies than

increasing confidence, we encourage public health policymakers to consider both beliefs and

behaviors patterns in their outreach efforts and information campaigns.

In sum, our model shows, in both mandate and inaccessibility scenarios, that the

probability of transmitting vaccine-positive attitudes is a strong predictor of whether future

vaccination coverage is high or low (**Figures 2, 4-5**). We also demonstrate that vaccine efficacy

and perceived value are important to maintaining sufficient levels of vaccination coverage,

especially if vaccine confidence is not being robustly transmitted (or maintained in adulthood),

regardless of vaccination scenario (**Figures 2, 4-5**). Thus, our model demonstrates the importance

of clear and accurate communication about vaccines even when vaccination is compulsory and

resulting coverage is high, to reduce the spread of inaccurate information that can foster vaccine

hesitancy and hinder the uptake of future vaccines.
