## 36 Abstract (242/250)

#### 37 Background

38 Households are an important location for severe acute respiratory syndrome coronavirus 2 (SARS-

CoV-2) transmission, especially during periods where travel and work was restricted to essential

- 40 services. We aimed to assess the association of close-range contact patterns with SARS-CoV-2
- 41 transmission.

## 42 Methods

- 43 We deployed proximity sensors for two weeks to measure face-to-face interactions between
- 44 household members after SARS-CoV-2 was identified in the household, in South Africa, 2020 2021.
- 45 We calculated duration, frequency and average duration of close range proximity events with SARS-
- 46 CoV-2 index cases. We assessed the association of contact parameters with SARS-CoV-2 transmission
- 47 using mixed effects logistic regression accounting for index and household member characteristics.

## 48 Results

- 49 We included 340 individuals (88 SARS-CoV-2 index cases and 252 household members). On
- 50 multivariable analysis, factors associated with SARS-CoV-2 acquisition were index cases with
- 51 minimum C<sub>t</sub> value <30 (aOR 10.2 95%CI 1.4-77.4) vs >35, contacts aged 13-17 years (aOR 7.7 95%CI
- 52 1.0-58.2) vs <5 years and female contacts (aOR 2.3 95%Cl 1.1-4.8). No contact parameters were
- associated with acquisition (aOR 1.0 95%Cl 1.0-1.0) for all three of duration, frequency and average
   duration.

## 55 Conclusion

- 56 We did not find an association between close-range proximity events and SARS-CoV-2 household
- 57 transmission. It may be that droplet-mediated transmission during close-proximity contacts play a
- 58 smaller role than airborne transmission of SARS-CoV-2 in the household, due to high contact rates in
- 59 households or study limitations.

- 62 and Development Office, United Kingdom.

#### 64 Introduction

65 South Africa has experienced five waves of severe acute respiratory syndrome coronavirus 2 (SARS-

- 66 CoV-2) infection, with over 4 million laboratory-confirmed cases by August 2022<sup>1</sup>. The true burden is
- highly underestimated, since based on seroprevalence data, after the third wave of infection, 43% to
- 68 83% of the 59.5 million South African inhabitants had already been infected, varying by age and
- 69 setting  $^{2,3}$ .
- 70 SARS-CoV-2 transmission is mainly via the respiratory route, with droplet-mediated transmission
- 71 thought to be the most important but airborne transmission also occurs <sup>4,5</sup>. Infection from
- 72 contaminated surfaces has also been described <sup>4</sup>. Although infection risk is highest from
- r3 symptomatic individuals <sup>6</sup>, with the most infectious period one day before symptom onset <sup>4</sup>,
- 74 asymptomatic individuals can still transmit SARS-CoV-2<sup>7,8</sup>. Households are a focal point for SARS-
- 75 CoV-2 transmission <sup>9,10</sup>, especially during peaks of non-pharmaceutical intervention (NPI)
- restrictions, when movement outside of the household was limited <sup>9</sup>. Transmission within
- households can in turn lead to spill over to the community  $^{11}$ .

78 Prior to the widespread availability of SARS-CoV-2 vaccines, most countries relied on NPIs to reduce the transmission of the virus, including wearing face masks, social and physical distancing. While 79 80 mobility and contact survey data showed that the implementation of NPIs led to a reduction in community contacts<sup>9,12</sup> and in turn opportunity for infection, it is still unknown what the role of 81 82 contact patterns are in the transmission of SARS-CoV-2 in the household. Most analysis relating contact patterns and SARS-CoV-2 transmission done to date has been based on low resolution data 83 collected from contact tracing <sup>13</sup>, mobility data <sup>9</sup> and contact surveys <sup>12</sup>. To obtain high-resolution 84 contact data, devices broadcasting and receiving radio frequency waves can be used to measure the 85 86 frequency and duration of close-proximity contacts. This has been used previously to collect contact data in among others, schools <sup>14</sup>, workplaces <sup>15</sup>, hospitals <sup>16</sup> and households <sup>17</sup>, which can, in turn, be 87 used for modelling disease transmission. Specifically, for SARS-CoV-2 so far, high-resolution contact 88 data were collected on cruise ships to identify areas of high contact, and to investigate the 89 90 usefulness of NPIs<sup>18</sup>.

- 91 Understanding the drivers of SARS-CoV-2 transmission in the household, especially contact patterns,
- 92 can help inform NPIs for future SARS-CoV-2 resurgences and potentially future emerging pathogens
- 93 with pandemic potential. We aimed to assess the association of household close-range contact
- 94 patterns with the transmission of SARS-CoV-2 in the household using proximity sensors deployed
- 95 after the identification of SARS-CoV-2 in the household.

## 96 Methods

## 97 Screening, enrolment and follow-up

- 98 We nested a contact study within a case-ascertained, prospective, household transmission study for
- 99 SARS-CoV-2, implemented in two urban communities in South Africa, Klerksdorp (North West
- 100 Province) and Soweto (Gauteng Province) from October 2020 through September 2021. Sample size
- 101 calculations were performed for the main study, but not the nested contact study. For the main
- 102 study we aimed to assess a significant difference in the household cumulative infection risk (HCIR)
- 103 between household contacts exposed to SARS-CoV-2 by a HIV-infected vs HIV-uninfected index case
- 104 for a 95% confidence interval and 80% power. The resulting total sample size was 440 exposed
- 105 household members. Detailed sample size calculations and methods for the main study have been
- 106 reported previously <sup>19</sup>. In short, symptomatic adults (aged  $\geq$ 18 years, symptom onset  $\leq$ 5 days prior)

107 consulting at clinics were screened for SARS-CoV-2 with real-time reverse transcription polymerase 108 chain reaction (rRT-PCR) on nasopharyngeal swabs. We enrolled household contacts of SARS-CoV-2 109 infected individuals identified through screening (presumptive index) with  $\geq 2$  household contacts of 110 whom none reported symptoms prior to index case onset. We visited enrolled households three 111 times a week to collect nasal swabs and data on symptoms and healthcare seeking. At enrolment 112 household characteristics (household size, number of rooms used for sleeping, smoking inside the 113 household and household income) and individual characteristics (demographics, education, 114 employment, smoking, HIV infection, underlying illness, if SARS-CoV-2 index case was main 115 caregiver, or sleeping in same room as index case) were collected. Nasopharyngeal (screening) and 116 nasal swabs (follow-up) were tested for SARS-CoV-2 on rRT-PCR using the Allplex™ 2019-nCoV kit 117 (Seegene Inc., Seoul, South Korea) and the first positive of each infection episode was characterised 118 using the Allplex<sup>™</sup> SARS-CoV-2 Variants I and II PCR assays (Seegene Inc., Seoul, Korea) and through 119 whole genome sequencing on the Ion Torrent Genexus platform (Thermo Fisher Scientific, USA). We 120 classified the infection episodes as Alpha, Beta, Delta, non-Alpha/Beta/Delta or unknown variant 121 where we were unable to classify the sample as a variant of concern due to primary testing done 122 elsewhere, low viral load or poor sequence quality. Households with multiple SARS-CoV-2 variants 123 circulating at the same time (mixed clusters) were excluded from the analysis. We also collected 124 serum at the first and final household visit for serological testing, using an in-house ELISA to detect antibodies against SARS-CoV-2 spike protein <sup>20</sup> and nucleocapsid protein using Roche Elecsys anti-125 SARS-CoV-2 assay. Individuals were considered seropositive if they tested positive on either assay. 126 127 Individuals sero-positive at the start of follow-up with no rRT-PCR confirmed SARS-CoV-2 infection 128 during follow-up were excluded from the analysis as they may have been protected from infection 21 129

#### 130 Contact pattern measurements

At the first or second visit during follow-up, we deployed wearable radio frequency (RF) proximity 131 sensors <sup>15</sup> for two weeks to measure close-range interactions (<1.5 meters) between household 132 133 members. The proximity sensors exchange low-power radio packets in the ISM (Industrial, Scientific 134 and Medical) radio band. Exchange of packets and Received Signal Strength Indicator (RSSI), suitably 135 thresholded, are used to assess proximity between the devices. A contact interval between two 136 devices is defined as a sequence of consecutive 20-second intervals within which at least one radio 137 packet was exchanged. Each sensor had a unique hardware identifier that was linked to participant 138 study identifiers. Sensors were worn in a PVC pouch either pinned to clothing on the chest, or on a 139 lanyard around the neck based on participant preference. We requested participants to wear the 140 device while at home, to store them separately from other household member sensors at night, and 141 to complete a log sheet every day for the periods the sensors were put on and taken off. During each 142 household visit during the sensor deployment period, field workers confirmed sensors were worn. A 143 deployment log was completed for each household to link the sensor identifier to the participant 144 identifier and to log the date and time sensors were deployed and collected. After sensor collection, 145 batteries were removed to prevent further package exchange between sensors. Sensors were 146 transported to the study office where each sensor was connected to a computer and data 147 downloaded.

148 Data analysis

149 We assumed the first individual with COVID-19 compatible symptoms in the household (individual 150 screened at clinic) was the index case. Any household member testing positive for SARS-CoV-2 151 within the two weeks from the last positive result for the index case was considered a secondary 152 SARS-CoV-2 case. Contact event data were cleaned using an automated pipeline. We excluded any 153 close-range proximity events outside of the deployment period and that occurred during a 5-minute 154 time slice that the accelerometer did not detect any movement of the sensor. Due to a technical 155 error, some sensors at the Klerksdorp site did not have a valid time stamp and needed additional 156 processing to align the time series of close-range proximity events. This was achieved by computing, 157 for each pair of tags X and Y, the temporal shift that maximizes the correlation between the time 158 series of the number of packets per unit time transmitted by X and received by Y, and the reciprocal 159 time series of the number of packets per unit time transmitted by Y and received by X (operation 160 that can be efficiently carried out working in the frequency domain via Fourier transformation). This 161 allowed us to build a temporal alignment graph between sensors and – as long as there was at least 162 one sensor with a valid timestamp in the household - to use such graph to propagate the valid 163 timestamp to all other sensors, thus recovering global temporal alignment. For the analysis, we only 164 considered close-range proximity events that occurred one day after deployment and one day 165 before collection. Where no timestamp was available, we used data collected from one to ten days 166 after deployment.

167 We assessed three contact parameters: 1) duration (median daily cumulative time in contact in 168 seconds), 2) frequency (median daily number of contacts with the index/infected individuals over 169 the deployment period) and 3) average duration (cumulative time in contact divided by the 170 cumulative number of close-range proximity events over full deployment period). Median values 171 were preferred over mean values due to the rightly skewed data, and the different number of days 172 with measured contact data for each household after data cleaning. We assessed contact 173 parameters in two ways: 1) median number of close-range proximity events with the presumptive 174 index case and 2) median number of close-range proximity events with all SARS-CoV-2 infected 175 household members (as confirmed by rRT-PCR). The latter assessment was to take into account that 176 the transmission could have been from any of the infected household members, and not necessarily 177 the index case, or that the index case was misclassified.

We constructed contact matrices by combining the median duration and frequency of close-range
proximity events for all participants between each age group, respectively. To normalize the matrix
based on number of participants, we divided the cumulative contact duration and frequency by the
total number of individuals in the two age groups being investigated in each cell.

182 We assessed the association of contact parameters with SARS-CoV-2 household transmission using 183 the Wilcoxon rank-sum test (considering p<0.05 as significant) and through logistic regression 184 controlling for individual characteristics associated with transmission. To assess factors associated 185 with SARS-CoV-2 household transmission, we performed logistic regression with a mixed effects 186 hierarchical regression model to account for household- and site-level clustering. For the analysis 187 with a defined index case (i.e. investigating close-range proximity events with all presumptive index 188 cases, first person with COVID-19 symptoms), we included only household contacts with their SARS-189 CoV-2 infection status as the outcome, assessing both index (transmission) and contact (acquisition) 190 characteristics. For the analysis with no defined index case (i.e. investigating close-range proximity 191 events with all SARS-CoV-2 infected household members), we included all enrolled household 192 members (originally considered presumptive index and household contacts), assessing only their 193 own characteristics. For the analysis with close-range proximity events with all SARS-CoV-2 infected 194 household members, we included an offset term in the model to account for the number of SARS-

- 195 CoV-2 infected members in contact with (number of nodes). We first built the model using individual
- 196 characteristics to assess factors associated with SARS-CoV-2 transmission (excluding contact
- 197 parameters). We included age and SARS-CoV-2 variant *a priori*, and assessed other co-variates on
- 198 univariate analysis, keeping those with p<0.2 in the multivariable analysis. For which we then
- 199 performed backwards elimination, keeping only those with p<0.05, and comparing each subsequent
- 200 model to the previous using a likelihood ratio test. Finally, we generated three separate models for
- 201 each analysis (index and infected household members), including each contact parameter to the
- final model to assess the association with transmission.

#### 203 Ethics

204 The study protocol was approved by University of the Witwatersrand Human Research Ethics

- 205 Committee (Reference M2008114). Participants in follow-up received grocery store vouchers of USD
- 206 3 per visit to compensate for time required for specimen collection and interview, and an additional
- 207 voucher once proximity sensors were returned with no visible damage.

## 208 Results

209 We screened 1,531 individuals and identified 277 (18%) positive for SARS-CoV-2, of which 124 (45%) were enrolled and included in the household cumulative infection risk analysis <sup>19</sup>, with 373 210 household contacts. After data cleaning, we had contact data for 88 (71%) index cases and 252 (68%) 211 212 household contacts (Supplementary Figure 1). Ninety-three individuals (19%, 36 index cases and 73 213 household contacts) were excluded due to non-compliance, where no contacts were logged, or 214 sensors was stationary for the period based on accelerometer data. We were more likely to have 215 contact data for individuals from the Soweto site, from larger households, and with no household 216 member reporting smoking indoors (Supplementary Table 1). The median number of household 217 members included in the analysis was 4 (inter quartile range [IQR] 3-5), with a median of 3 (IQR 1-4) 218 SARS-CoV-2 cases per household and a median of 67% (IQR 50-100%) of household members 219 infected (including index cases). Sixty-six percent (225/340) of individuals included in the analysis 220 lived in a household with 3-5 members, and 49% (168/340) lived in a home with only 1-2 rooms used 221 for sleeping, a third (53/340) living in households where crowding was reported (>2 people per 222 sleeping room, Supplementary Table 1).

- The overall median duration of daily close-range proximity events was 1,095 seconds (18 minutes, IQR 398-2,705 seconds), with a 39 second (IQR 32-49 seconds) average duration per contact event, and a median of 26 (IQR 10-58) close-range proximity events per day amongst household members (Figure 1, Supplementary Table 2). The highest median daily contact duration was observed between individuals within the <5 year, 5-12 year and 35-59 year groups (Figure 2 A, D). Similar patterns were also seen for median daily close-range proximity duration and frequency in children aged 5-12 and 13-17 years (Figure 2 B-F.
- 230 We did not find any association between any of the contact parameters (either with the index case 231 or all SARS-CoV-2 infected household members) and SARS-CoV-2 infection in the household using
- the Wilcoxon rank-sum test (p-values ranging 0.2-0.9, Table 1).
- 233 When assessing factors associated with SARS-CoV-2 transmission from presumptive index cases and
- 234 acquisition in household members, none of the contact parameters were associated with SARS-CoV-
- 235 2 transmission on univariate analysis. Sleeping in the same room as the index case was also not
- associated with transmission (OR 0.94, 95%CI 0.47 to 1.88). On multivariable analysis after
- 237 controlling for index age and SARS-CoV-2 infecting variant, factors significantly associated with
- higher SARS-CoV-2 transmission and acquisition was index case minimum C<sub>t</sub> value <30 (aOR 10.2

239 95%Cl 1.4-77.4) compared to  $C_t$  >35, contacts aged 13-17 years (aOR 7.7 95%Cl 1.0-58.2) compared

to <5 years and female contacts (aOR 2.3 95%Cl 1.1-4.8). Neither close-range proximity duration

241 (aOR 1.0 95%Cl 1.0-1.0), frequency (aOR 1.0 95%Cl 1.0-1.0) or average close-range proximity

duration (aOR 1.0 95%Cl 1.0-1.0) with the index case were associated with acquisition (Table 2).

243 When not considering transmission from the presumptive index case, but rather all SARS-CoV-2

244 infected household members, factors significantly associated with SARS-CoV-2 acquisition on

245 multivariable analysis after controlling for SARS-CoV-2 infecting variant were contacts aged 13-17

246 years (aOR 9.4 95%CI 1.2-75.9), 18-34 years (aOR 10.1 95%CI 1.3-76.0) and 35-59 years (aOR 8.8

95%Cl 1.1-67.7) compared to <5 years, being obese (aOR 4.1 95%Cl 1.5-11.1) compared to normal</li>
weight, and not currently smoking (aOR 3.2 95%Cl 1.2-9.2). Neither close-range proximity duration

weight, and not currently smoking (aOR 3.2 95%CI 1.2-9.2). Neither close-range proximity duration
 (aOR 1.0 95%CI 1.0-1.0), frequency (aOR 1.0 95%CI 1.0-1.0) or average close-range proximity

- 250 duration (aOR 1.0 95%Cl 1.0-1.0) with SARS-CoV-2 infected household members was associated with
- 251 acquisition (Table 3).

# 252 Discussion

In this case-ascertained, prospective household transmission study we did not find an association
 between the duration and frequency of close-range proximity events with SARS-CoV-2 infected
 household members with transmission in the household.

256 High-resolution contact patterns have been previously used to investigate influenza virus transmission routes in a hospital setting <sup>22</sup>, and contact surveys to show the association between 257 contacts, locations and influenza infection <sup>23</sup>, the high correlation between pneumococcal infection 258 risk and contact behaviour <sup>24</sup>, and in the context of tuberculosis transmission where contact with 259 adults are more important than contact with children <sup>25</sup>. To our knowledge, there are few data 260 available on the direct association of close-range proximity events and SARS-CoV-2, and none 261 262 making use of high-resolution contact data. During contact tracing efforts early in the pandemic in 263 Singapore, it was found that sharing a bedroom with an index case and speaking to the index case for more 30 minutes or longer increased the risk for infection <sup>26</sup>. We did not see similar results when 264 assessing sharing a bedroom with the index case, and this may be due to the already high level of 265 266 crowding in included households. Although we observed an increase in infection risk with higher 267 average contact durations with the index case on univariate analysis, this association was no longer 268 seen when adjusting for age and other index and contact factors associated with

269 transmission/acquisition.

270 There are several possible reasons why we did not observe an association with close-range proximity 271 events and SARS-CoV-2 transmission, these can be classified as related to transmission dynamics or 272 study limitations. One possibility is that along with droplet-mediated transmission during closeproximity contacts, airborne<sup>4,5</sup>, and to a lesser extent, fomite-mediated transmission<sup>4</sup> may also play 273 274 a role in the transmission of SARS-CoV-2 in the household. More evidence is becoming available 275 showing that aerosol transmission may be a more important transmission route for SARS-CoV-2 than initially anticipated, especially so in poorly ventilated indoor environments<sup>5,27</sup>. Households in these 276 communities do not have central air-conditioning or heating <sup>28</sup>, and during the winter months 277 ventilation may by poorer than in summer, although we did not measure this. Furthermore, sensors 278 279 only measure face-to-face interactions, and if individuals were close to each other but not directly 280 facing one another for extended durations, we would not have measured this, although sharing of 281 the same air may have occurred. The ventilation within households should be considered in future 282 studies, as this can be a target for intervention strategies to reduce secondary transmission. The high 283 level of interaction in relatively crowded South African households may already be above the

threshold for transmission risk, with host-characteristics like index viral load and contact age being more important to determine infection risk in this context. It is of interest that close-range proximity patterns within the household did not fully account for the differences in transmission based on age; with teenagers and adults experiencing the highest infection risk, but children aged 5-17 years having the highest contacts.

289 Our study had limitations both in design and execution. Due to the nature of the case-ascertained 290 study design, we would have missed the period when the index case was most infectious, just before 291 symptom onset<sup>4</sup>, and the close-range contact patterns measured during the study may have been 292 different after the household members were aware of the index SARS-CoV-2 case (leading to 293 reduced contact), and again once secondary cases were informed of their infection status (leading to 294 increased contact). We also did not collect any information on possible NPI usage in the households, like wearing of masks. A study from South Africa showed that individuals staying at home were less 295 likely to wear a mask <sup>29</sup>, but these data were not ascertained during a time when a household 296 297 member was infected with SARS-CoV-2. We also did not consider where contacts took place (indoors 298 or outdoors), which relates to ventilation and may have influenced transmission. We may have also 299 misclassified the true index case if they were asymptomatic, and did not consider tertiary 300 transmission chains in the index-directed analysis. To adjust for possible misclassification, we 301 performed a grouped assessment investigating close-range proximity events with all SARS-CoV-2 302 infected household members. This grouped analysis may also have diluted possible associations with 303 the true infector. We also did not consider multiple introductions within the household, although we 304 did exclude households with more than one SARS-CoV-2 variant detected. During the peaks of waves 305 of infection in South Africa, one variant was responsible for the majority of the infections <sup>30</sup>, and the additional introductions within the household were likely to have been the same as the initial 306 307 variant. Higher resolution sequencing data may be useful to more accurately identify chains of 308 transmission within the household. Combining contact data with clinical and 309 virological/bacteriological data have been shown to be useful to reconstruct transmission networks <sup>31</sup>, and we will consider this for future analyses. Our measurement of close-range contact patterns 310 311 was also limited by compliance, as during the cleaning process we identified 73 sensors that were 312 not worn, based on accelerometer data. We also had limited data in some households, where some 313 individuals did not consent to the contact aspect for the study, or where we were unable to retrieve

314 data due to hardware failure, lost or damaged tags.

315 In conclusion, we did not observe an association with close-proximity contacts and SARS-CoV-2 316 transmission in the household. A case-ascertained, prospective household transmission study may 317 not be well suited to investigate this question. A possible other study design to consider is randomly 318 selected prospective household cohorts, but deployment of sensors for extended periods of time 319 may be logistically challenging and lead to participant fatigue and households in a cohort may not 320 experience infection episodes unless the community attack rate is very high. High-resolution 321 contacts in other settings like schools or workplaces where contacts are less frequent could be 322 useful to identify the type of contact events that may lead to SARS-CoV-2 transmission. It may be 323 that aerosol transmission plays a more important role than droplet-mediated transmission, which 324 would make ventilation within households can also be an important consideration for future studies, 325 and increased ventilation can be a method to reduce secondary transmission in households. 326 Nevertheless, our study provides high-resolution household contact data that can be used to 327 parametrise future transmission models.

## 371 Tables

372	Table 1	Association of contact parameters with SARS-CoV-2 household acquisition*	' using the
572	Table 1.	Association of contact parameters with SARS-COV-2 household acquisition	using the

373 Wilcoxon rank-sum test, Klerksdorp and Soweto, South Africa, September 2020 – October 2021

Contact parameter	p-value
Median daily contact duration with index	0.82
Median daily contact frequency with index	0.71
Median daily average contact duration with index	0.22
Median daily contact duration with infected household members	0.25
Median daily contact frequency with infected household members	0.32
Median daily average contact duration with infected household members	0.95

\*Outcome investigated: testing positive for SARS-CoV-2

## Table 2. Factors associated with SARS-CoV-2 household transmission from index cases and acquisition in household contacts (contact parameters with index

376 case), Klerksdorp and Soweto, South Africa, 2020-2021, (n=252)
