Abstract: COVID-19 is associated with one of the largest disturbances to life in the 21st century. To quell disease spread, governments implemented lockdowns that likely created hardships for households. To improve knowledge of consequences, we examine how the pandemic period was associated with household hardships and assess factors associated with these hardships. We conducted a cross-sectional study using quasi-Poisson regression to examine factors associated with household hardships. Data were collected between August and September of 2021 from a random sample of 880 households living in a Health and Demographic Surveillance System (HDSS) located in the Harari Region and the District of Kersa, both in Ethiopia. Having a head of household with no education, residing in a rural area, larger household size, lower income and/or wealth, and community responses to COVID-19 including lockdowns and travel restrictions were independently associated with experiencing household hardships. Our results identify characteristics of groups at-risk for food insecurity during the pan-demic; households that were already struggling prior to the onset of the pandemic were at greatest risk of adverse consequences during the pandemic period. These findings may inform future efforts to mitigate the consequences of COVID-19 and future disease out-breaks.

Keywords: SARS-CoV-2; Africa; Resilience; Vulnerability

1. Introduction

The COVID-19 pandemic resulted in one of the largest disturbances to life in the 21st century. Beyond direct health effects,[1] the pandemic had social and economic consequences as government-enforced lockdowns were implemented to stem the pace and severity of the disease.[2] To adhere to these lockdowns, many businesses closed their in-person offices temporarily; for some, business closure was permanent. Mitigation efforts also affected healthcare providers who had to restrict in-person access to patients and/or limit services. These efforts may have affected the health of young children, pregnant women, and mothers by limiting access to healthcare and sufficient food—especially in isolated regions of resource-limited countries.[3-16] These indirect effects, in return, would exacerbate direct effects of the SARS-CoV-2 virus by increasing risk for undernutrition and other conditions that heighten the danger of serious illness. [14,15] Knowledge on the extent to which households living in resource-limited countries have experienced resource restrictions and other hardships remains limited due to incomplete or nonexistent population surveillance.[17]

In sub-Saharan Africa (SSA), national governments undertook considerable efforts to quell the spread of COVID-19.[2,18] Mitigation efforts in Ethiopia included social distancing, lockdowns, and emphasizing hygiene protocols; these efforts were started on March 16th of 2020, intensified on March 20th, and ultimately a state of emergency was declared on April 10th.[19] Economic and social disparities across different sociodemographic groups and geospatial inequalities may have resulted in uneven

implementation of these efforts.[11] These disparities may also have resulted in differential household
and community vulnerability to unintended consequences of these efforts.

Vulnerability is the collective effect of cultural, economic, institutional, political, and social processes
that modify the experience of and recovery from a given hazard.[20] In the context of disasters, it is
often not the hazard itself that creates the disaster; rather, the disaster is the impact on individual and
community coping patterns and the inputs and outputs of social systems.[21-23] Social vulnerability is
partially the result of social disparities that shape or influence the susceptibility of different groups to
hazards while also controlling their capacity to respond.[24,25] Individual and household level factors
often associated with vulnerability include demographic characteristics such as age, ethnicity, race,
and sex; socioeconomic status (e.g., income, wealth, employment, and/or education); household
composition (e.g., presence of children or elderly); and housing and transportation.[26] However, so-
cial vulnerability also involves place disparities stemming from characteristics of communities and the
built environment. For example, differential availability of scarce resources between urban and rural
areas may exacerbate individual and household level vulnerabilities to hazards.[27-29] To understand
the broader consequences of the pandemic, it is important to consider economic, political, and social
markers of vulnerability at the individual, household, and community level. [21-25]

In Ethiopia, those already burdened by social and economic disparities and limited in their ability to
access resources are at greater risk for experiencing additional hardships during the
pandemic.[7,11,18] Specific demographic groups disproportionately vulnerable include: older adults,
people with disabilities or pre-existing medical conditions, the poor, people living in congested resi-
dences and/or slums, pregnant women, and the unemployed. Rural populations in Ethiopia are at
elevated risk for food insecurity and agricultural hardships as climate change, severe drought, conflict,
and environmental degradation have culminated in societal shocks affecting livelihoods, particularly
for farmers.[30,31] Populations lacking access to safe drinking water and/or sanitary environments,
reliant upon emergency food aid, or with limited access to media or other communication technologies
are also at greater risk of adverse consequences of the pandemic.[18] Differential vulnerability requires
context specific interventions to address indirect costs of the pandemic.[32]

We used data from an existing Health and Demographic Surveillance System (HDSS) in Eastern
Ethiopia to analyze the prevalence of household level hardships experienced during the pandemic and
examine factors associated with vulnerability to these hardships. We further explore household re-
sponses to these hardships and analyze factors associated with households using these coping strate-
gies.

2. Materials and Methods

2.1. Study setting

The setting for this study is a predominantly rural area in the district of Kersa and an urban area in the
Harari People's National Regional State in Eastern Ethiopia.[33,34] The rural area consists of 24 kebeles
(a neighborhood or ward), and covers 353 km2 with a population of 135,754 in 25,653 households. The
urban area consists of 12 kebeles, a population of 55,773 in 14,768 households, across 25.4 km2. The
population has been followed through a Health and Demographic Surveillance System since 2012,
with demographic and health-related information regularly collected (see Figure 1).

Figure 1. The Harar and Kersa Health and Demographic Surveillance System (HDSS) in Eastern
Ethiopia. The smaller map panels on the right identify the location of the HDSS catchment areas
within Eastern Ethiopia.

2.2. Study design

This study is part of a larger examination within the Child Health and Mortality Prevention Surveil-
lance (CHAMPS) network to understand the consequences of COVID-19 lockdowns for child health
and mortality.[34] We administered a short data collection questionnaire designed to understand how
the pandemic and related lockdowns may have affected the livelihood, food availability, and
healthcare of households. Households were selected using simple random sampling to achieve a
sample size of 440 from the rural (Kersa) and from the urban (Harar) catchment areas (total sample
size of 880). The sample size was specified to detect prevalence of changes in accessing healthcare. A
priori specifications were 50% of the population experiencing changes, 95% CI, precision of 0.05 and
non-response adjustment of 10%.

The survey questionnaire was structured into five sections: knowledge regarding the spread of
COVID-19; food availability; COVID-19 related shocks/coping; under-five child healthcare services;
and healthcare services for pregnant women. Questions in the survey instrument related to hardships
associated with the pandemic period asked respondents to consider whether a given hardship had
occurred since March of 2020. Data collectors were drawn from the fieldwork teams of HDSS enu-
merators already trained and working in the HDSS. Data collection occurred between August and
September of 2021 and was carried out through tablet-based in-person interviews with adult house-
hold members. Survey data from the questionnaire were linked with data from the most recent HDSS
round to incorporate additional demographic data about the respective household: specifically, age,

sex, occupation, and education of the head of household; the number of children under 5 years of age
and the number of adults over age 60 in the household; and household assets and residence construc-
tion materials. Data quality assurance and cleaning followed standard procedures for the HDSS.[33,35]
Inconsistent or missing data were flagged for data collectors to correct. Field supervisors and the field
coordinator selected a random sample of questionnaires for re-visits to validate the recorded infor-
mation. Implementation of the module was approved by an Institutional Health Research Ethics Re-
view Committee (IHRERC); approval reference number Ref.No.IHRERC/127/2021.

2.3. Measures

The variable of interest *Household Hardships* was generated as an additive index of the number of
hardships a household reported experiencing during the COVID-19 pandemic (i.e., since March of
2020); it was coded as a count variable ranging from 0 to 9. Information on household hardships were
gathered from the following survey question: *"Has your household been affected by any of these events since*
mid-March?" Responses included: job loss; nonfarm business closure; disruption of farming; disruption
of livestock activities; disruption of fishing activities; increased price of farming or business inputs;
decreased price of farming or business outputs, increased price of major food items consumed; and
illness, injury, or death of any household member. The percentage of households that reported a given
hardship is presented in Figure 2. The additive index had a Cronbach's alpha score of 0.77 signifying
high internal consistency.[36]

132
Figure 2. Percentage of Households that Reported a Given Hardship. Represents the distribution of
hardships used in the additive index *Household Hardships* (n = 880).

To create an alternative representation of hardships, we used principal components analysis (PCA)
with varimax rotation to extract orthogonal factors from the variables in *Household Hardships*. The ei-
genvalues of the correlation matrix from PCA demonstrated that the first factor explained 40% of the
variability in the data and the second explained 20%. Subsequent factors explained little variability.
We opted to retain the first factor, which included job loss, nonfarm business closure, farm disruption,

livestock disruption, fishing disruption, and output inflation, as an index we termed *Household Dis-*
ruptions. Variables highly correlated with the factor were weighted against their eigenvector coeffi-
cients. Details related to the PCA results for the *Household Disruptions* are presented in Appendix A.

Right-hand side variables in our analyses included information on the head of household, character-
istics of the household and its homestead, and COVID-19 response variables. Head of household var-
iables were *age* (coded as 1 = less than 40 years, 2 = 41 to 44 years, 3 = 45 to 60 years, and 4 = sixty years
and above); *sex* (coded as male = 0 and female = 1); *ethnicity* (coded as Amhara = 1 (reference) and other
= 2, which included Oromo, Somali, Gurage, Harari and Tigray); *education* (coded as no formal educa-
tion = 0 (reference), any level of education = 1); *occupation* (coded as 1 = farmer/domestic (reference), 2
= student, 3 = professional, 4 = sales, 5 = daily laborer, 6 = other employment, 7 = unemployed/retired).
Household variables were *urbanicity* (coded as urban (Harar) = 1 and rural (Kersa) = 0); *household size*
(coded as 1 = 1-2 individuals (reference), 2 = 3-4 individuals, 3 = 5-6 individuals, 4 = 7-8 individuals, 5 =
9+ individuals); *children under age 5* (coded as 0 = no, 1 = yes); *adults over age 60* (coded as 0 = no, 1 = yes);
monthly *income* (coded as 1 = 0-1,200 Birr Ethiopia Birr (reference), 2 = 1,201-2,000 Birr, 3 = 2,001-3,000
Birr, 4 = 3,001-4,600 Birr, and 5 = 4,600+); and a *wealth index* based on a list of household assets (coded
as an 1 = poorest (reference), 2 = poorer, 3 = middle, 4 = richer, 5 = richest). For information on the
principal components analysis used to compute the wealth index see Appendix B. Covid response
variables were used to analyze associations between household hardships and communi-
ty/government interventions that were implemented to stem the severity of COVID-19. Responses
were gathered from the following survey question: *"What steps has your community/government taken to*
curb the spread of the coronavirus in your area?" Intervention variables analyzed include: *lockdowns, travel*
restrictions, business closures, and *intervention centers.* Each of these variables were coded Yes = 1 and No
= 0.

2.4. Analytic Strategy

Data cleaning and analysis was performed using R version 4.2.0.[37] Education and occupation related
data from the HDSS were missing for nine household heads; these households were removed from
analyses that included these variables. A series of unadjusted quasi-Poisson regression models were
used to analyze associations with the additive index *Household Hardships* and also with the PCA based
index *Household Disruptions* (results from the unadjusted analyses are available upon request). Ad-
justed quasi-Poisson regression models were then used to control for additional variables. Variables
were included in the final adjusted model if their inclusion had theoretical justification. We assessed
model fit with comparison of AIC and BIC scores—both scores were the smallest for the fully adjusted
model, indicating that this model had superior fit compared to simpler or pathway specific models.
Results are reported as Adjusted Incidence Rate Ratios (AIRR) with 95% confidence intervals (95% CI)
and visualized with forest plots.[38,39] Given anticipated differences in demographic, economic, and
social characteristics between populations living in urban vs. rural areas, effect modification was
evaluated using interaction terms and visualized as predicted probabilities. A secondary analysis was
conducted for those households that reported experiencing at least one hardship during the pandemic.
This analysis used adjusted logistic regression to examine factors associated with household responses
to pandemic hardships. We present results for the response strategies that were used by at least 10% of
households.

3. Results

Only 13% of households reported not experiencing any of the measured hardships; the remaining 87%
experienced at least one hardship (see Figure 3). The average number of hardships experienced during
the pandemic was 2.86 with a standard deviation of 2.31; the interquartile range spanned 1 to 4 hard-
ships. A majority of households (59.5%) observed an increase in local food prices (see Figure 2). Other
common hardships included a household member losing their job (55.5%), observing increases in the
cost of inputs for businesses or farms (49.8%), nonfarm business closures (30.2%), and reductions in the
value of business or farming outputs (27.8%).

b.

Figure 3. Number of Hardships Experienced during the COVID-19 Pandemic (n = 880). Figure 3a. presents a heat map of the number of hardships reported by the 880 sampled households. Figure 3b. presents the distribution of the additive index *Household Hardships*.

A majority of households (66%) were headed by a male household member (Table 1). Average age of the household head was 43 years with a standard deviation of 15. Roughly a quarter of household heads were from the Amhara ethnic group. A majority (58%) of household heads had obtained some level of education; their most common occupations were farmer (46%) and professional (27%). The median number of household members was 5 with a standard deviation of 2.4. Roughly a third of households reported having at least one child under the age of 5 and 27% of households had at least one adult family member over the age of 60. The most commonly reported government/community

responses to the pandemic were business closures (48%) followed by travel restrictions (46%) and the establishment of isolation centers (44%).

3.1. Factors Associated with Household Hardships

After adjusting for other variables (see Figure 4), households were more likely to report hardships
during the pandemic if the household resided in a rural compared to an urban area (AIRR = 1.34, 95%
CI [1.20, 1.49]). Compared to households with 1 to 2 household members, larger households were also
more likely to report hardships during the pandemic; for example, for households with 7-8 members,
the AIRR for experiencing hardships during the pandemic was 1.42 (95% CI [1.24, 4.65]). In contrast,
households were less likely to report experiencing hardships during the pandemic if the household
head had at least some education compared to none (AIRR = 0.87, 95% CI [0.79, 0.96]); was employed
in a professional occupation (AIRR = 0.75, 95% CI [0.66, 0.84]) or as a day laborer (AIRR = 0.74, 95% CI
[0.62, 0.88]) compared to employment in agriculture; had a monthly household income greater than
1,200 Birr (for example, the AIRR for experiencing hardships during the pandemic for households with
a monthly income greater than 4,600 Birr was 0.57 (95% CI [0.49, 0.66])); or were wealthier compared to
the poorest households. Households were also more likely to report experiencing hardships during
the pandemic if they also reported local community/government implementation of lockdowns (AIRR
= 1.29, 95% CI [1.14, 1.46]), travel restrictions (AIRR = 1.38, 95% CI [1.23, 1.56]), and the establishment
of isolations centers (AIRR = 1.17, 95% CI [1.03, 1.33]). The age, sex, and ethnicity of the household
head as well as the presence of children under the age of 5 or adults older than age 60 in the household
were not associated with household hardships after adjusting for other variables. Results from the
analysis of the *Household Disruptions* index (Figure 5) were generally consistent with the results from
analyzing the *Household Hardships* index.

Baseline predicted probabilities of household experiences with hardships during the pandemic based
on *urbanicity* (urban vs. rural residence) as well as probabilities estimated from models including in-
teraction terms with other variables are presented as a facet grid in Figure 6. The top facet presents the
elevated probability of experiencing hardships during the pandemic for households living in a rural
compared to an urban area while holding all other variables at their mean. These baseline probabilities
were estimated using results from the analytic model presented in Figure 5. The remaining facets
present predicted probabilities estimated from models that included statistically significant interaction
terms between *urbanicity* and other variables associated with *Household Hardships* while holding all
adjusting variables at their mean. The predicted probabilities indicate that households with a house-
hold head that identified as an ethnic group other than the Amhara or had no education were primar-
ily at greater risk of experience hardships if they were residing in a rural area compared to an urban
area. Dramatic dose responses of higher probability for experiencing hardships are seen for larger
households, households with lower income, and households with lower wealth that were residing in a
rural area compared to an urban area. In contrast, while the overall probability of experiencing hard-
ships was higher for households living in a rural area, local implementation of lockdowns and busi-
ness closures as a response to the pandemic were only associated with higher probability of experi-
encing hardships for those households living in an urban area.

Figure 5. Adjusted Associations with *Household Disruptions* presented as Adjusted Incidence Rate Ratios (AIRR). The forest plot presents AIRRs with 95% confidence intervals from a multivariate quasi-Poisson regression model. The AIRRs were adjusted for the other variables included in the model. Education and Occupation had 9 missing values; Income had one outlier set to missing. (n=870)

Figure 6. Evaluating Effect Modification between Urbanicity and other Factors Associated with *Household Hardships*. The figure presents a facet grid of predicted probabilities from multiple analytic models. The top facet presents the predicted probabilities for household residence in an urban (represented in green) vs. rural (represented in yellow) area, holding all other variables at their mean, to establish the baseline probabilities for households living in either of the two communities. The probabilities for this baseline were estimated using the results from the model presented in Figure 5. The remaining facets present predicted probabilities estimated from models that included interaction terms between urbanicity and other variables associated with *Household Hardships* while holding all adjusting variables at their mean.

3.2. Factors Associated with Household Responses to Hardships

The most common household response to experiencing at least once hardship during the pandemic was reducing food consumption, which was reported by 24.4% of affected households (see Figure 7). Other common responses included selling household assets (21.4%), seeking means to generate additional income (20.5%), seeking help from family or friends (14.0%), and borrowing from family or friends (10.6%).

Figure 7. Percentage of Households that Experienced a Given Hardship during the COVID-19 Pandemic (n = 766).

Comprehensive results for the analyses examining factors associated with household responses to pandemic related hardships are presented in Figures A1 – A5 (see Appendix C). After adjusting for other variables, including other potential hardships, households that had a member lose their job were more likely to report reducing food consumption (AOR = 1.75, 95% CI [1.06, 2.92]); selling assets (AOR = 3.19, 95% CI [1.30, 8.41]); seeking to generate additional income (AOR = 2.82, 95% CI [1.55, 5.25]); seeking help from family and friends (AOR = 2.20, 95% CI [1.28, 3.83]); and borrowing from family or friends (AOR = 5.80, 95% CI [2.61, 13.82]). Households that observed increases in the costs of business or farming inputs were more likely to report reducing food consumption (AOR = 2.77, 95% CI [1.51, 5.20]); selling assets (AOR = 9.24, 95% CI [3.82, 23.96]); seeking help from family and friends (AOR = 3.45, 95% CI [1.80, 6.82]); and borrowing from family or friends (AOR = 5.54, 95% CI [2.30, 14.06]). Observing increased food prices was associated with households selling assets (AOR = 2.36, 95% CI [1.12, 4.96]). Households that had a member close their business during the pandemic were less likely to report selling assets (AOR = 0.08, 95% CI [0.02, 0.29]). Households that experienced farming disruptions were more likely to report seeking to generate additional income (AOR = 24.79, 95% CI [7.26, 97.71]). Households residing in a rural vs. an urban area were more likely to use all of the measured strategies to mitigate experiencing hardships associated with the pandemic—these associations were robust to adjusting for other variables.

4. Discussion

In this study, we examined the prevalence of household hardships during the COVID-19 pandemic in a rural and an urban community in Eastern Ethiopia. We further examined demographic, economic, and social characteristic associated with these hardships as well as strategies households used to mitigate the severity of these hardships. Almost 90% of households reported experiencing at least one hardship since the onset of the pandemic; 75% of households reported experiencing at least 4 distinct hardships. Risk factors for experiencing these hardships included inequalities across demographic, economic, and social characteristics, but also place inequalities. Households that were already struggling prior to the onset of the pandemic were at greatest risk for experiencing additional hardships—residing in a rural area magnified the strength of the associations for several household level risk factors.

Households were more likely to report hardships if the head of household had no education or worked as a farmer or in a domestic/subsistence occupation. Households were also more likely to report experiencing hardships if they resided in a rural vs. an urban area, had a larger number of household members, had less monthly income, and were poorer compared to other households in the community. The pattern of association for both monthly income and household wealth is suggestive of a dose response; households with less wealth and less monthly income were at significantly higher risk for experiencing hardships. These associations are consistent with risk factors reported in studies from other resource limited countries and early stage research from Ethiopia.[6,10-13,18] Community responses to the pandemic associated with hardships included lockdowns and travel restrictions; business closures were only associated with experiencing hardships for households residing in an urban area. Future interventions that seek to mitigate negative consequences associated with pandemics mitigation efforts should anticipate these characteristics as important risk factors and target interventions to aid vulnerable groups.

Loss of employment for a household member and observation of increasing costs of business or farming inputs were both associated with the broadest combination of household responses to pandemic hardships. Patterns of association between demographic, economic, and social characteristics and household response strategies were inconsistent; however, compared to urban households, rural households were more likely to implement each of the measured response strategies, even after adjusting for demographic, economic, and social characteristics as well as the various pandemic related hardships.

The empirical findings from this study are not generalizable outside of the communities under study; while we acknowledge this limitation, we note that it is common to studies using HDSS data.[17] As an observational study, other potential limitations include unmeasured variable bias (for example, having data on household participation in Ethiopia's Productive Safety Net Program (PSNP) may have helped contextualize our results) or recall bias due to the extended length of time considered in the study (i.e., some respondents may have forgotten hardships that occurred closer to onset of the pandemic). As a cross-sectional study, we cannot draw causal inferences. Results from other studies suggest hardships associated with the COVID-19 pandemic are temporary.[7] Looking forward, scholars should collect and analyze longitudinal data to evaluate hardship events over time. In the context of demographic surveillance systems, follow-up data collection using the same survey instrument is easy to attach to subsequent rounds of data collection already being fielded. A further limitation, common to studies involving humanitarian crises, is that we are unable to differentiate between the effects of the pandemic and that of the political tension in the northern region of Ethiopia.[27] However, it is noteworthy that the northern region is more than 400 km away from the study communities.

5. Conclusions

Households living in the rural area of Kersa were at greater risk of experiencing a variety of hardships during the COVID-19 pandemic, even after adjusting for demographic, economic, and social risk fac-

tors. Moreover, the strength of the associations between household hardships and demographic, eco-
nomic, and social risk factors was greater for households residing in the rural area of Kersa compared
to the urban area of Harar. These results suggest an enduring urban vs. rural divide that amplifies the
effects of household level socioeconomic inequalities. Interventions seeking to ameliorate conse-
quences of lockdowns and other efforts implemented to stem disease spread should seek to address
place inequalities associated with rural areas as distinct from, but also interacting with, household
level risk factors. These finding may inform future policies and practices aiming to mitigate negative
consequences of COVID-19 and future disease outbreaks.

Eigenvalue	4.00
Explained variance	40%

Appendix B

Wealth Index Generation

A wealth index was generated based on a collection of assets and construction materials for the main
dwelling of a given household. To generate the index, we followed recommendations from the DHS
and the World Food Programme (WFP) that summarize steps for calculating an asset based wealth
index,[42-44] including coding instructions for Stata,[45] and an adaptation of this coding process im-
plemented in R.[29,46] Using these documents to guide us, we generated our wealth index by identi-
fying a list of household assets for inclusion in our index computation, recoded all household assets
into dichotomous variables; recoded dwelling materials into improved vs. non-improved dichoto-
mous variables; divided our sample into rural and urban subsamples and assessed level of represen-
tation of a given variable within the rural and urban subsamples (per WFP recommendations, a given
variable was included in further calculations if percent ownership ranged between 5 and 95 percent);
employed principal components analysis with varimax rotation to calculate component scores for
those households living in either rural or urban areas, which explained 45% of the variation in both
subsamples; extracted and combined the PCA scores of the first component from the urban and rural
subsamples; and finally organized the scores into wealth quintiles to generate a composite asset index.
The resulting wealth quintiles are presented in Figure (4). The distribution of assets owned by
households as well as the materials used for constructing a household's residence are presented as
percentages in Figure (5).
