Short title: The Mechanism of Effort Intolerance in Peripheral Arterial Disease.

Word count: 3941.

Abstract:

Background: Data to delineate exercise intolerance in patients with peripheral arterial disease (PAD) are scarce. We used a combined stress echocardiography and cardiopulmonary exercise test (CPET) to explore effort intolerance in PAD.

Methods: Twenty-eight patients who had both PAD and coronary artery disease (CAD) were compared with sex and age-matched 31 CAD patients and 15 normal controls using a symptom-limited ramp bicycle CPET on a tilting dedicated ergometer. Echocardiographic images were obtained concurrently with gas exchange measurements along predefined stages of exercise. Oxygen extraction was calculated using the Fick equation: $(VO_2)/(\text{echocardiography-calculated cardiac output})$ at each activity level.

Results: Along stages of exercise (unloaded; anaerobic threshold; peak), in PAD+CAD patients compared with CAD or controls: diastolic function worsened (E/e' 13.2 ± 3.1 vs 9.3 ± 2.4 vs 9.6 ± 4 ; 16.6 ± 4.3 vs 10.4 ± 2.5 vs 9.1 ± 3.8 ; 15.8 ± 4 vs 11.9 ± 2.9 vs 9.1 ± 4.1), and oxygen consumption (6.1 ± 1.4 vs 5.8 ± 1.9 vs 6.5 ± 2.5 ; 14.2 ± 1.8 vs 17.1 ± 2.9 vs 18.1 ± 3.3 ; 14.9 ± 2 vs 19.3 ± 2.5 vs 22 ± 3.6 ml/kg/min) and oxygen pulse (6.5 ± 1.9 vs 6.5 ± 2 vs 6.6 ± 2.3 ; 8.2 ± 1.8 vs 10 ± 2.4 vs 8.1 ± 2.3 ; 8.1 ± 2.2 vs 11.1 ± 2 vs 11.7 ± 2.6 ml/beat) were reduced. Notably, oxygen pulse was blunted due to an insufficient increase in both stroke volume (89 ± 11 vs 92 ± 11 vs 92 ± 13 ; 95 ± 10 vs 104 ± 9 vs 103 ± 11 ; 86 ± 10 vs 97 ± 10 vs 98 ± 11 ml) and oxygen extraction (0.06 ± 0.03 vs 0.07 ± 0.03 vs 0.07 ± 0.03 ; 0.09 ± 0.03 vs 0.12 ± 0.03 vs 0.12 ± 0.03 ; 0.09 ± 0.03 vs 0.13 ± 0.03 vs 0.13 ± 0.03 l/l). Chronotropic incompetence was more prevalent in PAD patients and persisted after correction for beta-blockers use (62% vs 42% and 11% respectively). Reduced ventilatory efficiency (peak VE/VCO_2 36.8 ± 4.9 vs 31.5 ± 4 vs 30.5 ± 5 l/l) and reduced mechanical efficiency (slope of oxygen consumption/work rate 8.96 ± 0.42 vs 10.37 ± 0.41 vs 10.8 ± 0.49 l/W) were found.

Conclusion: Exercise limitation is affected by diastolic dysfunction, chronotropic incompetence and peripheral factors in PAD patients.

Non-standard Abbreviations and Acronyms:

SE – stress echocardiography

CPET – cardiopulmonary exercise test

VO₂ – Oxygen consumption

VCO₂ – carbon-dioxide production

VE/VCO₂ – ratio of ventilation to carbon-dioxide production

RER – respiratory exchange ratio

AV difference – arteriovenous oxygen extraction

Clinical perspectives:

Peripheral arterial disease (PAD) is characterized by exercise intolerance. Yet, the mechanism behind this limitation is not well characterized. We show here that effort limitation in PAD is caused by a combination of central and peripheral cardiovascular factors including diastolic dysfunction, chronotropic incompetence and insufficient peripheral muscle oxygen extraction. These data may assist targeting future therapeutic measures.

Introduction:

Peripheral arterial disease (PAD) affects 6.5% of people aged 50-55 years in the western world and its prevalence reaches 13% in those aged 70-75 years.^{1,2} PAD is associated with a significant risk for cardiovascular outcomes, but is mainly characterized by effort intolerance which is usually associated with lower extremity pain.^{1,2} Nevertheless, studies exploring the mechanism behind effort intolerance in PAD are limited and therefore, it is difficult to delineate its drivers and to suggest targeted therapies. Here, we investigated effort intolerance in PAD with the use of a combined stress echocardiography (SE) and cardiopulmonary exercise test (CPET). Due to the high prevalence of coronary artery disease (CAD) in PAD patients^{3,4} and in order to adequately evaluate the effect of PAD, we used both CAD patients and normal controls as references.

Methods:

Study population:

Consecutive PAD patients who also had CAD (i.e. >70% obstructive epicardial coronary lesion⁵) underwent combined SE with CPET as part of investigation for effort intolerance at our center. Diagnosis of PAD was based on the following: extra-cranial carotid artery stenosis >50%, abdominal aortic aneurysm, ankle-brachial index (ABI) <0.9 or the need for peripheral arterial revascularization.¹ Patients were excluded from the study if they could not complete the exercise test (i.e. respiratory exchange ratio (RER) <1, n=7), had an abnormal echocardiographic exam (i.e. >moderate valvular heart disease (n=2), a left ventricular ejection fraction <40% (n=4)) or had severe pulmonary disease (n=1), leaving a total of 28 patients for the analysis ("PAD+CAD group"). Two groups of age and sex-matched patients who were referred for effort dyspnea assessment during the study period were used as controls: (I) patients with established CAD (of whom, 4 were excluded due to an inadequate exercise test and 4 were excluded due to abnormal rest echocardiography), leaving a total of 31 CAD patients ("CAD group"), and (II) 15 normal controls. All study participants were ambulatory and stable. The trial was approved by our local ethic committee and all patients signed an informed consent.

Study protocol:

The study protocol included a combined SE with CPET and was previously described.⁶

Cardiopulmonary exercise test:

A symptom-limited graded ramp bicycle exercise test was performed in the semi-supine position on a tilting dedicated microprocessor controlled eddy current brake SE cycle ergometer (Ergoselect 1000 L, CareFusion, San Diego, California). Expected peak oxygen consumption (VO_2 max) was the highest averaged 30-sec VO_2 during exercise and was estimated on the basis of patients' age, height, and weight. Work rate increment necessary to reach patients' estimated VO_2 max in 8 to 12 minutes was then calculated. The protocol included 3 minutes of unloaded pedaling, a symptom-limited ramp graded exercise, and 2 minutes of recovery. Breath-by-breath minute ventilation, carbon dioxide production (VCO_2), and oxygen consumption (VO_2) were measured using a Medical Graphics metabolic cart (ZAN, nSpire Health Inc., Oberthulba, Germany). The RER was defined as the ratio between VCO_2 and VO_2 obtained from ventilatory expired gas analysis.⁷ Anaerobic threshold (AT) was

determined manually using the modified V-slope method. Patients were encouraged to continue baseline medical therapy. In patients on beta-blocker therapy, chronotropic incompetence was determined when <62% of heart rate (HR) reserve was used.⁸

Stress echocardiography:

Rest stage echocardiographic images were taken before cycling. Then, echocardiographic images were obtained concurrently with breath-by-breath gas exchange measurements in a continuous manner along predefined stages of exercise: rest; unloaded cycling; AT; and peak exercise (i.e. VO₂ max). Each cycle of imaging included left ventricular end-diastolic and end-systolic volumes, stroke volume (SV), peak E- and A-wave velocities, deceleration time, and septal e', and lasted 30 to 60 sec. LV end-diastolic volume, end-systolic volume, and ejection fraction (EF) were calculated according to the single plane ellipsoid apical 4 chamber area-length method. Left atrial volume was calculated according to the biplane area-length method.⁹ SV was calculated by multiplying the LVOT area at rest by the LV outflow tract velocity–time integral measured by pulsed-wave Doppler during each activity level. All echocardiographic measurements were done using manual tracing.⁹ Echocardiographic data were then analyzed retrospectively at different exercise stages. Unloaded stage images were taken during unloaded exercise. AT (and the heart rate (HR) at the AT) were determined manually and retrospectively using the gas exchange measurements and the modified V-slope method. On the basis of HR at the AT echocardiogram, data were analyzed from the images captured immediately after reaching the HR at the AT. Peak exercise images were defined as those captured immediately after reaching RER >1.05.⁷ Arterio-venous oxygen extraction (A–VO₂) was calculated using the Fick equation as follows: (VO₂)/(echocardiography-calculated CO) at each activity level.¹⁰

Statistical analysis:

Categorical variables were summarized as frequency and percentage. Continuous variables were described as median and IQR. In order to compare clinical, echocardiographic and metabolic parameters in patients with PAD+CAD vs CAD or normal controls, the groups were first matched according to age and sex. McNemar test was used to compare categorical variables and Wilcoxon test was done to

compare continuous variables. To analyze the differences at the different stages of effort, we used the repeated-measures linear model analysis to define the within-group effect for each parameter over time, the between group differences over time, and the group by time interactions. All statistical tests were two sided and $p < 0.05$ was considered as statistically significant. SPSS software was used for all statistical analyses (IBM SPSS statistic for Windows, version 27, IBM corp., ARMONK, NY, USA, 2020)

Results:

The study group comprised 28 PAD+CAD patients. Mean age was 74.5 ± 7.1 , 81% men, 92% had a history of smoking, mean LVEF was $52 \pm 6.3\%$ and mean estimated glomerular filtration rate was 61.4 ± 8.1 ml/min. Differences in baseline characteristics between PAD+CAD patients and either CAD patients or normal controls are shown in Table 1. Notably, baseline LVEF (52.1 ± 6.3 vs 57.3 ± 4.5 vs $62.1 \pm 4.1\%$, $p = 0.021$ and $p < 0.001$), diastolic function (E/E' ratio: 12.1 ± 2.7 vs 10.2 ± 2.4 vs 8.3 ± 3.1 , $p = 0.023$ and $p = 0.012$) and pulmonary function tests (% predicted forced expiratory volume in 1 sec: 79.1 ± 16.8 vs 94 ± 15 vs 96.2 ± 17.7 , $p = 0.03$ and $p = 0.035$) were worse in PAD+CAD group vs CAD or normal controls, respectively.

Along stages of exercise (unloaded; anaerobic threshold; peak), comparing PAD+CAD patients vs CAD or controls: Cardiac output was reduced (7.4 ± 2 vs 7.5 ± 2.1 vs 7.8 ± 3.1 $p = 0.78$ and $p = 0.39$; 9.3 ± 2.7 vs 10.3 ± 2.4 vs 11.9 ± 2.8 $p = 0.10$ and $p = 0.002$; 10.5 ± 2.9 vs 12.7 ± 2.2 vs 13.2 ± 3.1 , $p = 0.032$ and $p = 0.0011$) due to a combination of blunted stroke volume increase (89 ± 11 vs 92 ± 11 vs 92 ± 13 , $p = 0.7$ and $p = 0.61$; 95 ± 10 vs 104 ± 9 vs 103 ± 11 , $p = 0.042$ and $p = 0.051$; 86 ± 10 vs 97 ± 10 vs 98 ± 11 ml, $p = 0.036$ and $p = 0.039$), impeded diastolic function (E/e' 13.2 ± 3.1 vs 9.3 ± 2.4 vs 9.6 ± 4 , $p = 0.0014$ and $p = 0.007$; 16.6 ± 4.3 vs 10.4 ± 2.5 vs 9.1 ± 3.8 , $p < 0.001$ and $p < 0.001$; 15.8 ± 4 vs 11.9 ± 2.9 vs 9.1 ± 4.1 l/m $p = 0.0027$ and $p < 0.001$) and diminished heart rate reserve (82 ± 12.6 vs 86.3 ± 13.2 vs 88.1 ± 14 , $p = 0.28$ and $p = 0.19$; 97.3 ± 14.1 vs 99.6 ± 13.3 vs 116.7 ± 15 , $p = 0.4$ and $p = 0.0013$; 107.7 ± 17.2 vs 119.8 ± 14.4 vs 138.5 ± 18.9 bpm, $p = 0.035$ and $p < 0.001$) which persisted after correction for beta-blockers use (chronotropic incompetence was present in 62% vs 42% and 11% of PAD+CAD vs CAD patients or controls, $p = 0.038$ and $p < 0.001$ respectively) (Table 2,

Figure 1, 2). Furthermore, oxygen consumption was reduced (6.1 ± 1.4 vs 5.8 ± 1.9 vs 6.5 ± 2.5 , $p=0.26$ and $p=0.19$; 14.2 ± 1.8 vs 17.1 ± 2.9 vs 18.1 ± 3.3 , $p=0.029$ and $p=0.0012$; 14.9 ± 2 vs 19.3 ± 2.5 vs 22 ± 3.6 ml/kg/min, $p<0.001$ and $p<0.001$) and oxygen pulse was blunted (6.5 ± 1.9 vs 6.5 ± 2 vs 6.6 ± 2.3 , $p=0.91$ and $p=0.63$; 8.2 ± 1.8 vs 10 ± 2.4 vs 9.8 ± 2.3 , $p=0.064$ and $p=0.085$; 8.1 ± 2.2 vs 11.1 ± 2 vs 11.7 ± 2.6 ml/beat, $p=0.0021$ and $p<0.001$) not only due to an insufficient increase in stroke volume, but also because of a reduced oxygen extraction (0.06 ± 0.03 vs 0.07 ± 0.03 vs 0.07 ± 0.03 , $p=0.22$ and $p=0.29$; 0.09 ± 0.03 vs 0.12 ± 0.03 vs 0.12 ± 0.03 , $p=0.041$ and $p=0.049$; 0.09 ± 0.03 vs 0.13 ± 0.03 vs 0.13 ± 0.03 l/l, $p=0.0015$ and $p=0.002$) (Table 2, Figure 1). Reduced ventilatory efficiency (peak VE/VCO_2 36.8 ± 4.9 vs 31.5 ± 4 vs 30.5 ± 5 respectively, $p=0.0031$ and $p=0.0018$) and reduced mechanical efficiency (slope of oxygen consumption/work rate 8.96 ± 0.42 vs 10.37 ± 0.41 vs 10.8 ± 0.49 respectively, $p<0.001$ and $p<0.001$, Figure 3) were found.

Discussion:

Using an elaborate protocol, we have demonstrated here that exercise limitation in PAD is associated with a combination of central and peripheral cardiovascular factors including diastolic dysfunction, diminished heart rate reserve and limited muscle oxygen extraction.

PAD is characterized by effort intolerance which is often associated with intermittent claudication and leg pain.¹¹ This intuitive association is strengthened by the beneficial effect of exercise training on walking distance and symptom improvement.¹²

Nevertheless, despite this clinical improvement, exercise training has little effect on indices of peripheral arterial function, such as ABI.¹³ This apparent contradiction might be settled given our findings showing that not only peripheral, but also cardiac factors are involved in the cardiovascular limitation in PAD.

Diastolic dysfunction:

PAD patients suffer from high prevalence of cardiovascular risk factor including diabetes mellitus and hypertension.^{1,2} Furthermore, CAD often coincides with PAD.^{4,}

¹⁴ All are in association with diastolic dysfunction. Nevertheless, baseline echocardiographic indices often do not fulfill diagnostic criteria for diastolic

dysfunction in PAD patients.¹⁵ Studies exploring effort intolerance etiologies have shown that diastolic dysfunction could be unmasked by exercise.¹⁶ Our findings suggesting "concealed" diastolic dysfunction in PAD which is exposed by exercise are in concordance with these results and may shed light on the attenuation in stroke volume and CO increase shown here. Notably, despite an overall similar risk profile in our CAD group, a diastolic limitation was less common in this group, suggesting that PAD+CAD patients may suffer from a higher prevalence of microvascular myocardial disease which may contribute to stress-induced diastolic dysfunction.¹⁷

Peripheral oxygen extraction:

Notwithstanding the important effect of CO on oxygen uptake along the exercise, we have shown here that peripheral oxygen extraction was reduced in PAD+CAD patients and contributed to oxygen uptake attenuation. A signal for this limitation was demonstrated as early as the unloaded pedaling phase. The importance and the contribution of peripheral oxygen extraction to total oxygen uptake increases as CO decreases¹⁸ and requires normal peripheral microvasculature and mitochondrial function, both compromised in PAD.¹⁹ Consequently, the combination of stroke volume attenuation shown here together with reduced peripheral oxygen extraction augments the limitation in total oxygen consumption and in exercise capacity in PAD.

Mechanical efficiency:

The combination of exercise-induced diastolic dysfunction, blunting of cardiac output and reduced peripheral oxygen extraction also corresponds with the reduced ratio of oxygen uptake to workload in PAD+CAD patients found in our study. Usually, a constant ratio of $\Delta O_2/\Delta W$ (usually around 10.5-11) is found in both normal and cardiovascular patients undergoing CPET studies. Nevertheless, a reduced ratio of $\Delta O_2/\Delta W$ characterizes high-risk patients (e.g. severe heart failure, pulmonary vascular disease) and might be caused from the presence of microvascular dysfunction, a change in the ratio of muscle fiber type or mitochondrial dysfunction. Different studies have shown that microvascular dysfunction is prevalent in PAD.^{20, 21} Furthermore, both pathology-based studies^{22, 23} and magnetic resonance imaging^{24, 25} have demonstrated a change in muscle characteristics and in mitochondrial function in PAD. Our results highlight these findings and emphasize the complex relationship between central and peripheral factors in PAD.

Chronotropic incompetence:

We have demonstrated here that PAD+CAD patients suffer from a high prevalence of chronotropic incompetence (CI). CI was repeatedly shown to be associated with increased morbidity and mortality in cardiovascular patients²⁶ and in this sense, our findings may shed light on another potential contributor to the poor outcomes shown in PAD. Additionally, CI is an important determinant of cardiac output and maximal oxygen consumption²⁷⁻²⁹ and further explains effort intolerance in PAD. Animal and human studies have demonstrated that PAD is associated with an increased sympathetic tone.^{30, 31} This may partially explain the limited "sympathetic reserve" and consequently, the CI which was observed here.

Our findings may contribute to potential therapeutic interventions in PAD. The main method of exercise training in PAD is supervised exercise program (SEP), which has demonstrated symptomatic improvement, improved quality of life and increased walking distance in PAD.³² It involves, however, at least 2-hours of weekly exercise for a 12-week period and therefore requires adherence which is not often achieved.³³ A potential alternative, high intensity interval training (HIIT), which was found beneficial in heart failure and in CAD, was not adequately evaluated in PAD.³⁴ It will be interesting to explore the potential cardiac vs peripheral cardiovascular effects of these two methods, an approach which may shed further light on our findings and their interpretation. Furthermore, our results showing a "concealed" diastolic dysfunction in PAD may imply that novel therapeutics (e.g. type 2 sodium glucose transporter inhibitors^{35, 36}) might prove to be beneficial in PAD. Similarly, the presence of microvascular dysfunction is highly likely in PAD and could be addressed by novel therapeutics.^{37, 38} Last, the CI demonstrated here was also found in HF and could be potentially mitigated by exercise training or implantable devices.

Our study has several limitations. First, we used a noninvasive approach for CO and filling pressures measurements and we calculated anaerobic threshold according to gas exchange alone. Nevertheless, our approach enabled us to examine "real-life" patients without the bias of including only those who agree to undergo an invasive procedure. Furthermore, the use of simultaneous echocardiography enabled us to measure dynamic changes in cardiac chambers' size and in valvular function. Second, our study group was comprised of PAD+CAD patients and not PAD alone. We

believe, however, that the very high prevalence of CAD in PAD patients cannot be ignored and our approach makes our findings more translational to everyday clinical practice. Third, our age and sex-matched normal control group was comprised of elderly patients with low-intermediate prevalence of cardiovascular risk factors. Nevertheless, comparing our high-risk study group with a group of young and healthy controls might have damaged the validity of our findings.

In conclusion, using a comprehensive cardiopulmonary and stress echo test, we have demonstrated that exercise intolerance in PAD is associated with diastolic dysfunction, chronotropic incompetence and reduced peripheral oxygen extraction. Further studies are needed to establish targeted therapeutic approaches which might mitigate these limitations.

Figure legends:

Figure 1 – Along stages of exercise, oxygen consumption was reduced in PAD patients due to a combination of mechanical and peripheral limitations.

P* - PAD+CAD vs CAD, P[#] - PAD+CAD vs Normal controls.

Figure 2 – Compared with either CAD patients or normal controls, a higher prevalence of chronotropic incompetence was found among PAD+CAD patients.

Figure 3 – A decreased ratio of oxygen consumption to work rate was shown in PAD+CAD patients compared with either CAD patients or normal controls.
