Is there a bilingual advantage in auditory attention among children? A systematic

review and meta-analysis of standardized auditory attention tests

Abstract

A wealth of research has investigated the effects of bilingualism on cognition, especially on executive function. Developmental studies reveal different cognitive profiles between monolinguals and bilinguals in (audio-)visual attention tasks, which might stem from their attention allocation differences. Yet, whether such distinction exists in the auditory domain alone is unknown. In this study, we compared differences in auditory attention, measured by standardized tests, between monolingual and bilingual children. A comprehensive literature search was conducted in three electronic databases: OVID Medline, OVID PsycInfo, and EBSCO CINAHL. Empirical studies using standardized tests to assess auditory attention in monolingual and bilingual participants aged less than 18 years were included. Among the 20 studies identified, we performed a meta-analysis and found that test measure (accuracy vs. response times) was significantly related to differences in effect sizes whereas other factors (e.g., participant age, stimulus type) were not. Specifically, studies reporting accuracy observed a marginal bilingual advantage ($g = 0.10$), but those reporting response times indicated a small monolingual benefit ($g = -0.34$). Therefore, there was little difference between monolingual and bilingual children's performance on standardized auditory attention tests. We also found that studies tend to include a wide variety of bilingual children but report limited language background information of the participants. This, unfortunately, limits the potential theoretical contributions of the reviewed studies. Recommendations to improve the quality of future research are discussed.

Introduction

Over the past decade, the growing body of research investigating the effects of bilingualism on cognition suggests that bilingual experience can shape the brain and cognitive systems [1, 2]. Some studies [3, 4] demonstrate that bilingual participants outperform their monolingual counterparts on a wide range of cognitive tasks while controlling for other factors, which is often interpreted as a bilingual advantage. For example, bilingual children develop conflict resolution ability earlier than monolinguals and perform better on memory tasks based on executive control [3] (but see [5] for equal performance in inhibitory tasks).

Cognition has many facets, among which executive function (EF) is most frequently measured in bilingual developmental studies [6]. Recent meta-analyses present mixed results about whether bilingualism confers an EF benefit in children. Gunnerud et al. [7] analyzed 143 studies examining different EF components in children aged 18 months through 14.5 years; no bilingual advantage was found in overall EF after adjusting for publication bias. Similarly, Lowe et al. [8] reported a negligible effect of bilingualism on overall EF ($g = -0.04$) in children aged between 3 and 17 years. However, using the Bayesian statistical approach, Grundy [9] revealed that when group differences do appear on EF tasks, bilinguals outperform monolinguals far more likely than chance. Given these discrepant findings, the bilingual advantage appears small at best and might be subject to specific circumstances [10]. However, what these "circumstances" are remains unclear.

Addressing whether a general bilingual advantage exists is beyond the scope of this study. We do not intend to engage in a dichotomous discussion to this debate, as it oversimplifies the effects of bilingualism on cognitive development. Nevertheless, we acknowledge that bilingualism can confer certain cognitive benefits at least in some types of bilinguals, which has

been supported by empirical studies [11, 12]. Further, attention has been hypothesized to be a

plausible domain responsible for the bilingualism effects [2]. That is, the habitual use of two

languages over years possibly enables bilinguals to become more practiced in managing conflicts

and controlling attention. In particular, early bilingual exposure can affect how attention is

allocated to the environment. For instance, infants growing up in bilingual homes pay more

attention to subtle environmental differences [13, 14], which could improve their attentional

processing [15].

76   However, a definition of attention remains vague in cognitive literature. Here, we

conceptualize it as a system with three primary components: sustained attention, selective

attention, and executive control [16, 17]. Specifically, based on Petersen and Posner [16],

sustained attention (or alerting) refers to maintaining alertness over a long period of time, which

is usually measured in the form of vigilance tasks that involve monitoring a target stimulus

interspersed with non-targets. *Selective attention* (or orienting) refers to the ability to select

certain input for enhanced processing while suppressing other irrelevant information, and thus is

often measured by focusing on the target stimuli and ignoring the distractors. Lastly, *executive*

control deals with resolving conflicts, shifting attention, and regulating thoughts and behavior.

These components are also associated with different neural substrates in the human brain [16].

86   Visual or audio-visual attention has been primarily studied in bilingualism research,

suggesting that bilingual experience modulates attention allocation [18, 19]. Auditory attention,

however, has received little consideration, despite its importance to language processing and

development: language is often processed through the auditory domain alone (e.g., speech

perception), and infants start learning about language in utero without any visual support [20].

Likewise in the visual domain, bilingualism might also affect how auditory attention is allocated

in bilingual children.

The current systematic review and meta-analysis assess whether there are reliable

differences in auditory attention, measured by standardized tests, between monolingual and

bilingual children. An initial search in our laboratory indicates that standardized tests are often

used to assess children's auditory attention in research and clinical settings [21], and are an ideal

comparison across labs given consistent administration guidelines. These tests target different

auditory attention components and use different types of auditory stimuli, which are either

linguistic or non-linguistic (see Results for further information).

As attention might support monolingual and bilingual development differently [2],

investigating auditory attention in monolingual and bilingual children will illuminate different

adaptations to their language environments. Additionally, examining the bilingualism effects on

auditory attention will address the current literature gap by focusing on the auditory domain,

which has been overlooked in prior attention research. Our prediction is that if auditory attention

development is shaped by bilingual experience, monolingual and bilingual children would

perform differently on standardized tests; considering the bilingual advantage hypothesis,

bilinguals might perform better.

An additional goal of our study is to determine whether certain bilingual characteristics

(e.g., age of acquisition, language proficiency) mitigate the potential differences between

monolinguals and bilinguals. Since cognitive advantages tend to appear in more proficient

bilinguals [11, 12], we hypothesize that simultaneous bilinguals (i.e., children who learn both

languages before the age of three) would more likely show enhanced auditory attention than

sequential bilinguals (i.e., children who learn additional languages after the age of three). Finally,

given that it is unclear whether bilingualism exerts influence beyond linguistic domain and

standardized tests vary by stimulus type (linguistic vs. non-linguistic), we will assess if different

auditory stimuli affect attention performance in monolingual and bilingual children.

Materials and methods

This study is part of a larger systematic review that investigates auditory attention

development from infancy to adolescence, in which the population's language experience (i.e.,

monolingual vs. bilingual) and research methods are not controlled. The review protocol was

registered a priori with OSF [21]. We followed the *Cochrane Handbook for Systematic Reviews*

of Interventions [22] as the methods guidance, and developed the search strategy in consultation

with a health sciences librarian. A PRISMA (Preferred Reporting Items for Systematic Reviews

and Meta-Analyses) flow diagram illustrating the screening process is presented in Fig 1. The

methods described below are specific to our current (more focused) literature search embedded

in Bao and Molnar [21].

Fig 1. PRISMA flow diagram presenting the study screening process.

Eligibility criteria

To include the most relevant studies on auditory attention measured by standardized tests,

we adhered to the following criteria when determining a study's eligibility:

● Studies that used standardized tests to measure auditory attention were included.

Standardized tests are norm-referenced tests administered and scored in a consistent

manner. Studies using non-standardized measures or focusing on visual attention and

other cognitive abilities were excluded.

● Studies that tested typically developing individuals below the age of 18 and had a

monolingual group and a bilingual group were included. The bilingual group should be

raised in bilingual families or study in immersion schools where most of the curriculum is

taught in an unfamiliar language. Studies only having monolingual or bilingual

participants were excluded.

● Studies that controlled for participants' age and socio-economic status (SES) were

included, as both factors can affect children's cognitive measures independently [23].

● Published, empirical studies that reported primary results in peer-reviewed articles were

included.

● Given the reviewers' capabilities, only articles written in English were included.

Information sources and search

A comprehensive literature search was conducted in three electronic databases: OVID

Medline, OVID PsycInfo and EBSCO CINAHL. Search terms were defined after consulting the

librarian and tailored to each database (see S1-S3 Tables). The search contained articles from the

databases' start date up to March 8, 2023. Based on the search result of the larger systematic

review, we identified all studies that compared monolingual and bilingual performance on

standardized auditory attention tests. In addition, a manual search was performed by checking

the reference lists of relevant articles, and an updated manual search was undertaken in Google

Scholar to identify more studies.

Study selection

Records and data were managed using the Covidence systematic review software [24].

Duplicates were identified and removed during reference importing and screening. Two

independent reviewers screened studies in two phases: (1) title/abstract screening required to

indicate "Yes," "No" or "Maybe" for relevance; (2) full-text screening required to indicate

"Include" or "Exclude" for eligibility and specify the exclusion reasons. If discrepancies

occurred, a third reviewer was called to resolve the conflicts.

Data collection

For eligible studies, two independent reviewers extracted the following data items on

Covidence: (1) sample size (monolingual vs. bilingual); (2) participant age; (3) language

background (first and second language), bilingual type (simultaneous vs. sequential), and

bilingualism assessment; (4) standardized tests used to assess auditory attention; (5) test measure

(accuracy vs. response times or RTs); (6) stimulus type (linguistic vs. non-linguistic); (7)

auditory attention components measured; (8) reporting of SES. In the case of unclear or missing

items, we contacted the investigators to confirm and obtain additional information. Afterwards, a

third reviewer built consensus on extracted data.

Data analysis

Apart from a narrative synthesis of included data, we built meta-regression models to

analyze the studies' effect size using the "metafor" package (version 3.0-2) [25] in R [26].

Specifically, the dependent variable was the unbiased estimate of the population effect size

Hedges' g, calculated for each study. The independent variables were test measure (binary:

accuracy vs. RTs), stimulus type (binary: linguistic vs. non-linguistic), participant age

(continuous, in years) and attention components (categorical: selective attention, sustained

attention, executive control, or auditory attention overall). To evaluate the effects of these

predictors, we conducted model comparison in a forward stepwise manner: a likelihood ratio test

was performed using the *anova* function to compare a reduced model and a full model, which

had one additional component. If the resulting *p*-value was less than the conventional threshold

of 0.05, the full model provided a better fit for the data. Otherwise, the reduced model was

favored. Information criterion statistics (e.g., Akaike's Information Criterion or AIC, Bayesian

Information Criterion or BIC) were inspected for both models (with lower values indicating a

better model performance), and BIC is preferred over AIC when the heterogeneity is large in the

studies [27]. For categorical variables that significantly predicted the effect size, subgroup

analyses were conducted using the "meta" package (version 5.2-0) [28] and forest plots were

generated to visualize the effects.

Furthermore, publication bias was analyzed for the included studies by means of the

funnel plot, created using the "meta" package. The funnel plot displays the studies' effect size

against its standard error. Usually, symmetry indicates the absence of publication bias, which is

reflected by data points scattered around the mean effect size forming an upside-down funnel.

This symmetry was further quantified through Egger's regression test.

Results

Synthesis

The database search yielded 634 records for title/abstract screening. Forty articles

remained for full-text review, and three articles qualified for extraction. Our manual search

contributed another nine articles, four of which did not appear in the database search as they

were not indexed. In total, 12 articles were extracted, which included 20 studies.

Population characteristics

With an age range between 5 to 14 years, participants can be categorized into

preschoolers (5-6 years), primary school-aged children (7-11 years), and young adolescents (12-

14 years). This categorization has considered different education systems across countries. For

example, while primary school starts at the age of four in the Netherlands, the first two years are

comparable to kindergarten. Therefore, the five-year-old children in Boerma et al. [29] and

Kwakkel et al. [30] were treated as preschoolers. Table 1 presents a detailed description of all

participants. Taking language background for an example, there are a great variety of first and

second languages, with French-English and Spanish-English being the most common language

combinations within bilinguals.

Table 1. Descriptive statistics of included studies.

Study	Country	Monolingual (*n*)	Bilingual (*n*)	Age (mean; years)	First language; second language	Bilingual type	Bilingualism assessment	Standardized test	Test measure	Stimulus type	Attention component	SES

Test; ACPT-P: Auditory Continuous Performance Test-Preschoolers; TEA-Ch: Test of Everyday Attention for Children; TAP: Test

for Attentional Performance; NEPSY(-II): A Developmental Neuropsychological Assessment (Second Edition); SAAT: Selective

Auditory Attention Test.

Numbers following the names signify individual studies from the same article.

*Asterisk indicates that the bilingual type was not directly reported by the investigators but inferred from the original articles

However, there was not sufficient information about bilingual characteristics in the

reviewed papers. For instance, bilingual type (simultaneous vs. sequential) was rarely reported,

except that Karlsson et al. [31] and Krizman et al. [32, 33] recruited "early bilinguals." Usually,

bilingual children were from immigrant families learning the societal language as their second

language (L2) [29, 34], or enrolled in immersion schools acquiring a foreign language [35-38].

Note that for longitudinal studies, we considered participants' language condition when they

were tested. For example, Nicoley and Poncelet [37] collected data at two time points; data from

the second one (i.e., three years after immersion school enrollment) were included only, because

children cannot be deemed bilingual yet during the initial testing when they just started the

program. Generally, immersion school children were considered sequential bilinguals, as most of

them were from a monolingual environment and did not learn an L2 until they started school.

Additionally, bilingual experience was often evaluated using parental questionnaires that focus

on one aspect (e.g., language use, exposure, or proficiency), which led to inconsistent definitions

of bilinguals and the difficulty of comparing them across studies.

SES was reported in all studies, and mostly assessed through education level of the

mother or both parents (parental occupation was also used occasionally, e.g., Garratt and Kelly

[34]). Monolingual and bilingual participants had a comparable SES across articles, except in

Simonis et al. [38] where the bilingual group had a higher SES than the monolingual group.

Given no significant difference on test performance between the two groups, this article was

included in final analysis.

Test characteristics

Various standardized tests (see Table 1) were used to assess auditory attention.

Considering how they were described in the included studies, we categorized them into the

following three groups: (1) Test for Attentional Performance (TAP) [39], Test of Attentional

Performance for Children (KiTAP) [40], and Selective Auditory Attention Test (SAAT) [41]:

assess *selective attention*; (2) Integrated Visual and Auditory Continuous Performance Test (IVA

+ Plus) [42], Auditory Continuous Performance Test for Preschoolers (ACPT-P) [43], and Test

of Everyday Attention for Children (TEA-Ch) [44]: assess *sustained attention*; (3)

Developmental Neuropsychological Assessment (NEPSY) [45] and its second version (NEPSY-

II) [46]: assess *auditory attention overall* (selective and sustained attention, and executive

control). For tests evaluating audio-visual attention, we included data from subtests using only

auditory stimuli. Further, we found that both linguistic and non-linguistic stimuli were utilized.

For example, some tests used non-linguistic stimuli like auditory tones (TAP) and animal sounds

(KiTAP; e.g., [35, 38]), whereas others employed linguistic stimuli such as numbers (IVA +

Plus; TEA-Ch), speech syllables (ACPT-P), and words (NEPSY, NEPSY-II, SAAT; e.g., [29,

32, 33, 47]). Though it remains unknown whether different types of auditory stimuli affect

attentional performance.

Moreover, some researchers used translated versions (e.g., Swedish version of NEPSY-II

in [31]) or adapted the tests [38], and reported the assessed attention components differently. For

example, modelled after ACPT-P, Foy and Mann [48] used an auditory Go/No-Go task with two

blocks. We infer that the first block assessed sustained attention and the second one evaluated

executive control, as the authors did not explicitly report the attention components. Using the

same task, however, Kwakkel et al. [30] stated that they measured "sustained attention."

Another source of variance we observed involved the test measure reported. All studies

presented either accuracy or RTs, except that Simonis et al. [38] did both. Nevertheless, how

accuracy was reported in different studies was not always consistent, even for the same test. For

instance, Garratt and Kelly [34] reported standard scores for the Auditory Attention and

Response Set subtests of NEPSY together, whereas Karlsson et al. [31] reported raw scores for

each subtest of NEPSY-II individually. Simonis et al. [38] used decimal numbers to indicate

accuracy (i.e., 1 = 100% accuracy), whereas Kwakkel et al. [30] used reversed omission scores.

Despite these discrepancies, for all accuracy statistics in this meta-analysis, larger values indicate

better auditory attention. However, we did not include data that were presented in other forms

and could not be converted to accuracy scores or proportions, e.g., misses in Foy and Mann [48]

and errors in Barbu et al. [35]. When sufficient statistical details were not reported in a given

study, we contacted the investigators to obtain them. Alternatively, we used WebPlotDigitizer

[49] to extract data from graphs in Krizman et al. [32].

Meta-analysis

Effect size was analyzed using meta-regression modelling. We first built a mixed-effects

model, with each study's effect size as the dependent variable and test measure as the moderator.

Model summary suggested that test measure significantly influenced the studies' effect size ($p =$

0.0067; see S4 Table). Further, results of a subgroup analysis confirmed that there was a

significant difference in effect size between studies reporting accuracy (i.e., accuracy studies)

and studies reporting RTs (i.e., RT studies; $p = 0.0014$; see S5 Table). Fig 2 shows a forest plot

stratified by test measure: a marginal bilingual advantage was found in accuracy studies ($g =$

0.10), whereas a small monolingual benefit was observed in RT studies ($g = -0.34$). However,

results favored monolingual children ($g = -0.09$) in standardized auditory attention tests when

taking both measures together.

Fig 2. Forest plot stratified by test measure, based on random-effects model analysis. The

upper and lower panels display the results for accuracy studies ($n = 12$) and RT studies ($n = 8$),

respectively.

To investigate the effects of other variables, we divided our data into two subsets (i.e.,

accuracy studies and RT studies) and analyzed them separately. For accuracy studies ($n = 12$), a

meta-regression model with participant age as the predictor was built. Age did not influence the

effect size significantly ($p = 0.1282$; see S6 Table). However, a positive trend favoring young

bilingual adolescents was observed (see S1 Fig). Following the same approach, we tested the

effects of stimulus type and attention components, but neither of them was significant (stimulus

type: $p = 0.9550$; attention components: $p = 0.4865$; see S7 and S8 Tables). For RT studies ($n = $

8), none of the variables above was significant (participant age: $p = 0.2056$, stimulus type: $p = $

0.5494, attention components: $p = 0.9396$; see S9-S11 Tables). In addition, there was not

substantial publication bias in our data according to the funnel plot (S2 Fig), which was further

confirmed by the result of Egger's regression test ($p = 0.414$; see S12 Table). However, we did

not include unpublished research, which is a potential limitation.

Discussion

The current systematic review and meta-analysis analyzed 20 studies that compared

monolingual and bilingual children's performance on standardized auditory attention tests.

Results suggest that test measure was significantly related to differences in effect sizes, with a

marginal bilingual advantage in accuracy studies ($n = 12$) and a small monolingual benefit in RT

studies ($n = 8$). However, no other factors (i.e., participant age, stimulus type, attention

components) resulted in significant differences or interactions. In answer to the question in the

title, a bilingual advantage in auditory attention, when measured using standardized tests, likely

does not exist or is restricted to certain conditions (e.g., accuracy measure or more proficient

bilinguals). To be fair in our interpretation of this finding, two points should be considered: (1) a

very heterogeneous bilingual population was synthesized across studies, wherein bilingualism

was poorly assessed; (2) most standardized tests are developed for monolingual English speakers,

thus they might not be suitable to measure bilinguals. As far as we know, there is no clear

theoretical framework where we could place our results directly or interpret possible bilingual

advantages [50]. Our work may contribute to building such models by highlighting the relation

between bilingualism and auditory attention.

320   In the reviewed papers, standardized auditory attention tests were administered to

participants as young as five years of age, and to children (5-11 years) more often than to young

adolescents (12-14 years). Monolingual children seemingly had faster RTs, but bilingual children

showed somewhat higher accuracy. Prior work from other domains than auditory attention has

presented mixed findings about the RT difference between groups. On one hand, Bialystok et al.

[51] used the Simon task—a non-linguistic interference task—and observed faster latency in

bilingual children, although this effect was later only found when the demands for inhibitory

control were high [52]. On the other hand, some language processing tasks report longer RTs in

bilingual adults. For example, bilinguals have slower RTs to target words during a lexical

decision task [53], and perform more slowly in a picture naming task than monolinguals [54].

These linguistic tasks specifically measure cross-language interference and switching, and

bilinguals' slower RTs have been often associated with their need to navigate more than one

language system.

333   In our study, bilingual children seemed to have slightly more accurate responses, but at

334 the cost of longer latency relative to their monolingual peers. However, these findings should be

335 interpreted with caution, because most accuracy and RT measures were derived from different

336 studies across the reviewed articles. Only Simonis et al. [38] reported both measures, but neither

337 accuracy nor latency showed group differences between monolingual and bilingual children in

338 their study. To draw a firm conclusion on the relationship between accuracy and RTs, one should

339 only consider studies that report both measures within the same group.

340   With regards to the measured auditory attention components, selective attention and

341 sustained attention are mostly assessed, followed by executive control. While one may argue that

342 it is hard to disentangle these components and measure them independently, we distinguished

343 them by considering the specific tasks used by investigators and the attention model developed

344 by Posner and colleagues [16]. We also noticed inconsistency across publications when reporting

345 the measured components with a given test. For example, using the auditory section of IVA +

346 Plus, Krizman et al. [33] measured "attentional control," whereas Boerma et al. [29] assessed

347 "sustained attention." This observation is in line with Williams et al. [6] who also found

348 variation in targeted cognitive abilities for the same task in bilingualism research.

349   Moreover, rarely were sufficient details about participants' bilingual background

350 reported. This is problematic because differences in language experience (e.g., age of

351 acquisition, proficiency; [4, 55]) can affect cognitive performance. For example, more proficient

352 bilinguals tend to exhibit a cognitive advantage. Consistent with this, we observed a trend of the

353 bilingual advantage toward adolescents relative to younger children, which can be explained by

354 the fact that bilingual children become more proficient in their languages when growing older.

In addition, bilingualism was poorly assessed and hardly deemed a continuum. We

identified two common themes: (1) most language background questionnaires fail to assess

bilingualism comprehensively (i.e., including the use of, exposure to, and proficiency of each

language; see [32]); (2) bilingual participants are usually recruited as a comparison group to

monolinguals, without explaining inclusion criteria. This practice overlooks the nuances within

bilinguals. For example, an English L2 learner from Spain is not comparable to a Spanish

heritage speaker from the U.S., although both considered as Spanish-English bilinguals. Thus,

variance in different bilingual communities should be considered, captured, and reported in

future work.

In future studies, bilingualism should be considered as a continuum, and bilingual

variables should be appropriately assessed and reported. This will facilitate our understanding of

how various facets of bilingualism interact with auditory attention development. Moreover,

further investigation should test monolinguals and bilinguals across age groups and report both

accuracy and RTs. Given that most tests are designed for monolingual English speakers, we also

advocate for developing tests that are normed to assess both monolinguals and bilinguals. Lastly,

there was little consistency regarding the targeted attention components even for the same test

across publications, which may be due to the lack of a clear definition of attention in the field

itself. Therefore, we need to consider further what attention along with its components refers to

in (bilingualism) research and theoretical models.

Supporting information

S1 Checklist. PRISMA 2020 checklist.

S1 Fig. Forest plot stratified by participant age groups, based on random-effects model analysis. Green lines represent accuracy studies, and blue lines represent RT studies. A bilingual advantage in young adolescents is shown.

S2 Fig. Contour-enhanced funnel plot. Effect size (i.e., standardized mean difference or SMD) is plotted against its standard error. Each dot represents an individual study. Grey-shaded areas indicate different p-value intervals.

S1 Table. Search terms used in the electronic databases under the concept of "auditory attention".

S2 Table. Search terms used in the electronic databases under the concept of "population".

S3 Table. Search terms used in the electronic databases under the concept of "study types and methods".

S4 Table. Mixed-effects model summary, with test measure as the moderator.

Identification of studies via databases and manual search

Identification

Electronic database searches:
OVID Medline (n = 8605),
OVID PsycInfo (n = 6055),
EBSCO CINAHL (n = 5455)

Records identified in total (n = 20115)

Duplicate records removed *before screening* (n = 3487)

Screening

Titles / abstracts screened (n = 16628)

Irrelevant records excluded (n = 15491)

Full-text articles assessed for eligibility (n = 1137)

Records excluded: (n = 1067)
Wrong population: not focusing on typically developing children (n = 467)
Wrong outcomes: not focusing on auditory attention (n = 500)
Wrong study type: not empirical studies (n = 36)
Not written in English (n = 49)
Study unavailable (n = 13)
Duplicate (n = 2)

Included

Articles included in review (n = 70)

Articles fitting current inclusion criteria (n = 3)

Articles identified through manual search (n = 9)

Articles included in the analysis: (n = 12)
Studies included in the analysis: (n = 20)
