ABSTRACT

INTRODUCTION: The reliability and validity of self-reported cardiovascular and cerebrovascular risk factors remains inconsistent in aging research.

METHODS: We assessed the reliability, validity, sensitivity, specificity, and percent agreement of self-reported hypertension, diabetes, and heart disease, in comparison with direct measures of blood pressure, hemoglobin A1c (HbA1c), and medication use in 1870 participants in a multiethnic study of aging and dementia.

RESULTS: Reliability of self-reported for hypertension, diabetes, and heart disease was excellent. Agreement between self-reports and clinical measures was moderate for hypertension (kappa: 0.58), good for diabetes (kappa: 0.76-0.79), and moderate for heart disease (kappa: 0.45) differing slightly by age, sex, education, and race/ethnic group. Sensitivity and specificity for hypertension was 88.6%-78.1%, for diabetes was 87.7%-92.0% (HbA1c \geq 6.5%) or 92.7%-92.8% (HbA1c \geq 7%), and for heart disease was 85.8%-75.5%.

DISCUSSION: Self-reported history of hypertension, diabetes, and heart disease are reliable and valid compared to direct measurements or medication use.

Introduction

Cardio- and cerebrovascular risk factors are frequent among elderly adults and their presence is associated with increased risk of Alzheimer's disease^{1,2}. Self-reported questionnaires are often used to gather information about antecedent risk factors, including cardiovascular and cerebrovascular risk, for Alzheimer's disease in observational studies^{2,3} due to convenience and lower cost relative to clinical diagnosis⁴. It is the only feasible way of obtaining information on the disease in the absence of clinical or medical records. However, the reliability, validity and overall accuracy of self-reports may be affected by the participant's understanding of the diagnosis, willingness to report it, and ability to recall their personal information, which can be of concern among elderly individuals⁴. Well-validated and reliable self-reported information of disease risks is important for understanding the cause of the disease and may provide clues to preventive strategies.

Hypertension, diabetes, and heart disease are major cardiovascular risk factors leading increased burden of cardiovascular and cerebrovascular diseases^{5,6} and risk of dementia and Alzheimer's disease^{1,2}. The validity of self-reported information in these vascular risk factors assessed from several studies^{3,4,7-15} were found to be uncertain and highly variable reflecting differences in study population, sociodemographic characteristics, and the use of clinical measurements or treatments. There is limited information available on the reliability and validity of self-reported hypertension, diabetes, and heart disease among racially and ethnically diverse older adults.

The Washington Heights, Hamilton Heights, Inwood Columbia Aging Project (WHICAP) is a community-based longitudinal study of aging and dementia in elderly individuals living in northern Manhattan^{16,17}. This cohort includes older adults who identify as non-Hispanic Black or African American, Caribbean Hispanic, and non-Hispanic White, and it also provides an opportunity assess differences by educational level, sex, clinical and genetic factors in relation to age-related

diseases¹⁸. We previously reported higher prevalence and incidence rates of cerebrovascular disease and dementia among non-Hispanic Black and Hispanic older adults compared to non-Hispanic white individuals in WHICAP^{17,19}. Thus, understanding whether the reliability and validity of self-reported vascular risk factors differs by racial and race/ethnic group is an important objective.

Among older participants in this multi-ethnic community-based WHICAP cohort, the validity of self-reported hypertension, diabetes, and heart disease was investigated using Cohen's kappa, sensitivity, specificity, and percent agreement by comparing participant responses to direct measurements or reviewing disease-specific medications use. We also investigated the reliability of self-reports using longitudinal data, and whether the validity of self-reported hypertension, diabetes, and heart disease differed by age, sex, education, or race/ethnic group.

Methods

Participants. Participants were from WHICAP, a community-based longitudinal study of aging and dementia in a multiethnic cohort of individuals aged 65 years or older residing in northern Manhattan^{16,17}. Participants were initially recruited as non-demented by self-report in waves in 1992, 1999, and 2009 using similar sampling strategies, assessments, and study design and procedures¹⁷.

Consent Statement. The study was approved by the Institutional Review Boards of Columbia University. All participants provided written informed consent. A detailed description of the study was previously published¹⁶.

Cardio- and Cerebrovascular Risk Factors (Vascular Risk Factors). At the initial and each follow-up visit, self-reported medical history, self-reported use of disease-specific medications, and physical examinations were recorded. Self-reported information on hypertension, diabetes, and heart disease was obtained from each participant at last visit by three questions “Have you ever had a hypertension / diabetes / heart disease?” (Ever Had or Never Had).

Clinical measures were also obtained by direct measurement in a subset of the most recent WHICAP participants and from available information obtained at the interviews. For hypertension we used two approaches. First, we used the measurement of blood pressure defined as systolic blood pressure ≥ 140 mmHg, diastolic blood pressure ≥ 90 mmHg²⁰, based on the WHO guidelines²¹. If no measurement of blood pressure was available, we used information regarding the use of anti-hypertension medications. For diabetes we considered two reference definitions: *definition 1*: measurement of hemoglobin A1C level $\geq 6.5\%$ at last visit or the use of any medications to manage diabetes at the initial or follow-up visits; *definition 2*: hemoglobin A1C level $\geq 7\%$ at last visit or diabetes medication use at the initial or follow-up visits. Cut-points for hemoglobin A1C level were based on the current American Diabetes Association guidelines²² ($\geq 6.5\%$) and current Department of Veterans Affairs’ recommendations ($\geq 7\%$)^{23,24}. For heart disease we relied entirely on the use of medications to manage heart disease at the initial or follow-up visits. The use of medications was classified as follows: *Hypertension*: angiotensin-converting enzyme inhibitors, beta-blockers, calcium channel blockers, or diuretics; *Diabetes*: glitazones, insulin, metformin, oral hypoglycemics, or sulfonylurea; *Heart disease*: digitalis or digoxin, anti-anginal agents, nitrates, or other anti-arrhythmics/anginals. The reported use of medications was recorded as “Taken or Not Taken”.

Covariates. Information on age at last visit, sex, education and race/ethnic group were queried. Years of education was self-reported and ranged from 0 to 20. The determination of race/ethnic

group was self-reported using the 2000 US Census²⁵ as a guide. We excluded the small number of individuals who did not identify as non-Hispanic Black, Caribbean Hispanic or non-Hispanic white (n = 24).

Statistical analyses. Reliability^{26,27} of self-reported hypertension, diabetes, and heart disease was assessed at the individual level for participants with at least two visits by fitting a mixed effects logistic regression model with fixed effects including age, sex, educational level, and ethnicity and a random intercept for each individual using rpt function in R package rptR²⁶. We assessed the reliability of each self-reported vascular factor beginning from the first interview at which there was an affirmative response. We also investigated the reliability of self-reported risk factors at the individual level for participants with at least two visits excluding the first negative reports if they later had a positive self-report. The repeatability value ranges from 0 to 1 and the value of less than 0.40 was considered poor, 0.40-0.59 as fair, 0.60-0.74 as good, and 0.75-1.00 as excellent reliability.

Validity of self-reported risk factors data was compared to measured hypertension, diabetes and heart disease using Cohen's kappa²⁸, sensitivity²⁹, specificity²⁹, and percent agreement²⁸. Cohen's kappa was used to measure the agreement between self-reported and measured risk factor by taking into account the agreement expected to occur by chance. The kappa value ranges from -1 to 1 and the value of less than or equal to 0 was considered no, 0.01-0.40 as poor-to-fair, 0.41-0.60 as moderate, 0.61-0.80 as good, and 0.81-1.00 as excellent agreement²⁸. Sensitivity was defined as the proportion of participants who self-reported to ever had a risk factor among those with positive measured risk factor. Specificity was defined as the proportion of participants who self-reported to never had a risk factor in whom we found no evidence of the measured risk factor. False negative rate (1-sensitivity) and false positive rate (1-specificity) were used to examine the proportion of under-reported and over-reported, respectively, for risk factors. Percent

agreement was defined as the proportion of all participants with positive self-report with positive measured risk factor or negative self-report with negative measured risk factor²⁸. We compared the percent agreement for hypertension, diabetes, and heart disease.

Stratified analyses of the validity measures for self-reported hypertension, diabetes, and heart disease were subsequently compared across several demographic variables (age, sex, education, and race/ethnic group). Participants were stratified by median age of 80.9 years, younger (65 years \leq age <80.9 years) and older (age \geq 80.9 years). Participants were categorized into three groups of educational level using cut-points based on the education quartiles of the samples, low (education < 6), medium (6 \leq education < 12), and high (education \geq 12 years of education)³⁰. Exact method³¹⁻³³ was used to compute the confidence intervals. Kappa statistic and its confidence interval were computed using epi.kappa function in R package epiR³⁴. Sensitivity and specificity and its confidence intervals were computed using BDtest function in R package bdpv³⁵. Difference between two proportions was tested using two-proportions z-test using prop.test function in R package stats³⁶. A p-value less than 0.05 was considered significant. The false discovery rate (FDR) of 0.05 was used to correct for multiple testing. All statistical analyses were performed using R³⁶ version 4.1.3.

Results

A total of 1,870 participants were 65 years or older and had complete data on self-reported and measured hypertension, diabetes and heart disease, in addition to age at last visit, sex, education, and race/ethnic group. The demographics characteristics of this cohort are in **Table 1**. The

frequency of self-reported vascular risk factors: hypertension, diabetes, and heart disease are also listed in **Table 1** and **Supplementary Table 1**. The clinical measures showed a higher frequency of hypertension ($p < 0.001$) and lower frequencies for diabetes ($p = 0.030$ for *definition 1* and $p = 0.003$ for *definition 2*) and heart disease ($p < 0.001$) than the self-reported assessments.

The 1,870 participants had a total of 4,743 self-reported hypertension assessment and 4,739 self-reported diabetes and heart disease assessments at the initial and follow-up visits. Of those, when we restricted to participants with at least two visits, 1,307 participants had self-reported hypertension assessment with a total of 4,183 visits, 1,306 participants had self-reported diabetes with a total of 4,178 visits, and 1,307 participants had self-reported heart disease with a total of 4,179 visits (**Supplementary Table 2**). We excluded the first negative self-reports of participants when they later had positive self-report due to a change in health status, after restricting to participants with at least two visits, 1,240 participants had self-reported hypertension with a total of 3,860 visits, 1,269 participants had self-reported diabetes with a total of 3,985 visits, and 1,222 participants had self-reported heart disease with a total of 3,795 visits (**Supplementary Table 2**). The self-reported hypertension, diabetes, and heart disease were assessed from three visits per individual on average. The distribution of the proportion of positive self-reported risk factors among individuals is shown in **Supplementary Table 2**.

The reliability of self-reports was excellent for hypertension (0.96 and 0.97), diabetes (0.98 and 0.99), and heart disease (0.95 and 0.95) unadjusted and adjusted for age, sex, education, and ethnicity, respectively (**Table 2**). The subsequent reliability of self-reports was excellent for hypertension (0.987), diabetes (0.995), and heart disease (0.986) when unadjusted and adjusted for age, sex, education, and ethnicity (**Table 2**).

The validity of self-reported against measured hypertension, diabetes, and heart disease is shown in **Table 3**. The agreement between self-reported and measured vascular risk factors was moderate for hypertension (kappa: 0.58, 95% confidence interval (CI): 0.53-0.63), good for diabetes (kappa: 0.76, 95% CI: 0.73-0.80 for *definition 1*; kappa: 0.79, 95% CI: 0.76-0.82 for *definition 2*), and moderate for heart disease (kappa: 0.45, 95% CI: 0.40-0.50). Our agreement for diabetes was higher than that of hypertension ($p_{FDR}=0.013$ for *definition 1*; $p_{FDR}=0.004$ for *definition 2*) and heart disease ($p_{FDR}<0.001$ for *definition 1* and 2). Sensitivity and specificity for hypertension was 88.6% (95% CI: 86.9-90.1) and 78.1% (95% CI: 73.0-82.7), that of diabetes for *definition 1* was 87.7% (95% CI: 84.0-90.7) and 92.7% (95% CI: 91.2-94.0), that of diabetes for *definition 2* was 92.0% (95% CI: 88.8-94.5) and 92.8% (95% CI: 91.4-94.1), and that of heart disease was 85.8% (95% CI: 81.7-89.3) and 75.5% (95% CI: 73.3-77.7), respectively, resulting in over-reporting and under-reporting of 21.9% and 11.4% for hypertension, 7.3% and 12.3% for diabetes for *definition 1*, 7.2% and 8.0% for diabetes for *definition 2*, and 24.5% and 14.2% for heart disease. Percent agreement for hypertension, diabetes, and heart disease were 87%, 92% for *definition 1* and 93% for *definition 2*, and 77%, respectively, and diabetes had a higher percent agreement than hypertension ($p_{FDR}<0.001$) and heart disease ($p_{FDR}<0.001$) for *definition 1* and 2.

When stratified by sex, age, education, or race/ethnic group, the sensitivity of hypertension was higher for older, than younger adults (91.5% vs. 85.6%, $p=0.0003$) and higher for women, than men (90.3% vs. 85.2%, $p=0.004$) (**Table 3**). Specificity of hypertension was higher for non-Hispanic Whites, than Hispanics (89.7% vs. 71.9%, $p_{FDR}=0.007$), that of diabetes was higher for participants with high education, than low education (95.2% vs. 90.2%, $p_{FDR}=0.006$ for *definition 1*; 95.3% vs. 90.4%, $p_{FDR}=0.006$ for *definition 2*), that of diabetes was higher for non-Hispanic white individuals, than Hispanics (95.7% vs. 90.8%, $p_{FDR}=0.015$ for *definition 1*; 95.8% vs. 90.8%, $p_{FDR}=0.013$ for *definition 2*), and that of heart disease was lower for older, than younger adults (72.2% vs. 78.5%, $p=0.006$). Percent agreement of hypertension was higher for older, than

younger adults (89.6% vs. 84.3%, $p=0.001$) and higher for women, than men (88.8% vs. 83.6, $p=0.002$), that of diabetes was higher for participants with high education, than medium education (94.4% vs. 90.9%, $p_{FDR}=0.046$ for *definition 2*) and higher for non-Hispanic white individuals, than non-Hispanic Black participants and Hispanics (95.2% vs. 91.7%, $p_{FDR}=0.038$; 95.2% vs. 91.8%, $p_{FDR}=0.038$ for *definition 2*), that of heart disease was lower for older, than younger adults (75.2% vs. 79.6%; $p=0.026$). There were no significant differences in Cohen's kappa, sensitivity, specificity, and percent agreement of the risk factors for the other strata.

Discussion

This investigation assessed the reliability of self-reported vascular risk factors and the validity when compared with directly measured hypertension, diabetes, and heart disease in a community-based study of older individuals of African and Hispanic ancestry, and non-Hispanic white individuals of European ancestry. We found excellent reliability of self-reported hypertension, diabetes, and heart disease with and without adjustment for age, sex, education, and ethnicity. We also found good agreement between self-reports of vascular risk factors and measured HbA1c, and moderate agreement for measured hypertension and medication use for heart disease. Sensitivity, specificity, and percent agreement were high for diabetes and moderate for hypertension and heart disease. In stratified analyses, sensitivity and percent agreement of hypertension were highest in older adults and women. The specificity of hypertension and diabetes was slightly higher in non-Hispanic white individuals compared with Hispanic individuals. Individuals with more education also had higher specificity for diabetes. The specificity of heart disease was lowest for the oldest individuals. Percent agreement of diabetes for was higher among individuals with more education, and higher in non-Hispanic white individuals, than African-Americans or Hispanics.

The agreement for hypertension was consistent with prior studies in older adults^{8,10-12}, as was the sensitivity^{7,9,11,13}. The sensitivity for non-Hispanic white (85%) and non-Hispanic black individuals (91%), and Hispanics (89%) were similar to previously reported older US-born adults¹³. The specificity and the percent agreement of self-reported hypertension was consistent with prior studies^{7,9,11,13}. It is possible that these participants were 15-20 years older than in previous studies^{7,9,13} and perhaps more accustomed to reporting the presence of hypertension³⁷⁻³⁹.

For diabetes, reliability as measured by the kappa for both categories of HbA1c was consistent with prior studies in older adults^{8,11,12,40}. The sensitivity, specificity percent agreement were similar to prior studies^{4,9,11,12,40,41}, but only a few studies compared self-reported diabetes with hemoglobin HbA1c^{8,12,40}. The intensive intervention, lifestyle management in terms of diet and exercise, and use of medications required for diabetes may explain the higher awareness of diabetes¹¹.

The agreement for heart disease was consistent with previous studies¹⁰⁻¹² of myocardial infarction and heart failure^{7,9-12}. Self-reported heart failure has been difficult to validate compared with clinical measures throughout the literature⁴². The low agreement may reflect the complexity of diagnosing and classifying various types of heart disease and conveying these diagnosis to patients⁴². Despite these limitations, the sensitivity was reasonable and within the range of previous reports on myocardial infarction and heart failure^{7,9,11,12}. The specificity and the agreement were lower than that observed in previous studies^{7,9,11,12}. A possible explanation for the difference was the definition of heart disease. Medical documentation was not available for the heart disease in this study. This required that we rely entirely on the reported use of medications to manage all types of heart disease. Another explanation could be limited knowledge about types of heart disease¹². It has been shown that awareness for heart failure is lower than for other heart conditions in the general population⁴³.

Previous studies have investigated the validity of self-reported cardiovascular risk factors in populations at risk for stroke^{4,18}. Similar to our investigation, data were extracted from questionnaires and compared with direct measurements or medical records. Overall accuracy was best for hypertension and diabetes, but not for hypercholesterolemia. The sensitivities for hypertension reported in other studies reviewed by Bowlin et al⁴⁴ were slightly lower than those reported here. However, high sensitivity and specificity were found in older non-Hispanic Blacks, Hispanics and non-Hispanic Whites in the Health and Retirement Study¹³. This suggests that the accuracy of self-reported vascular risk factors is variable but not limiting.

Strengths of our study include the use of a large, well-characterized, longitudinal, multi-ethnic cohort that allowed us to evaluate the reliability and validity of self-reported risk factors among a diverse group of older adults. Moreover, the use of HbA1c to assess the validity of self-reported diabetes is important because using this measure is recommended for the diagnosis of diabetes by the American Diabetes Association²².

Despite these strengths, our study is subject to potential limitations. The study was conducted in older population aged 65 years or older living in northern Manhattan with a high frequency of cardio- and cerebrovascular risk factors. This may have limited generalizability to other age groups or cohorts with lower morbidity. The medical documentation of heart disease was not available and we relied entirely on self-reported medication use. This may have resulted in lower specificity and lower percent agreement than the previous literatures. Hispanic individuals have fewer years of education than non-Hispanic Black and non-Hispanic White individuals, which can affect the accuracy of self-report⁴⁵.

Our results indicate that there is excellent reliability among older individuals for self-reported hypertension, diabetes, and heart disease. Furthermore, agreement, sensitivity, specificity, and

percent agreement of self-reported diabetes were good and that of hypertension and heart disease were moderate when using clinical measures as validation. Establishing reliability and validity will also augment efforts to harmonize data across similar epidemiological studies.

Table 1. Participant demographics and clinical characteristics of the study sample.

Characteristic	Total Sample (n=1,870)
Age (years), mean, median (SD)	81.16, 80.9 (7.18)
65 ≤ Age < 80.9, n (%)	847 (45%)
Age ≥ 80.9, n (%)	1023 (55%)
Sex	
Women, n (%)	1212 (65%)
Men, n (%)	658 (35%)
Education (years), mean (SD)	9.39 (4.79)
Low: Education < 6, n (%)	436 (23%)
Medium: 6 ≤ Education < 12, n (%)	616 (33%)
High: Education ≥ 12, n (%)	818 (44%)
Race/ethnic group	
Non-Hispanic white, n (%)	483 (26%)
African American, n (%)	635 (34%)
Caribbean Hispanic, n (%)	752 (40%)
Self-reported	
Hypertension, n (%)	1459 (78%)
Diabetes, n (%)	462 (25%)
Heart disease, n (%)	670 (36%)
Measured	
Hypertension, n (%)	1573 (84%)
Diabetes (<i>definition 1</i>), n (%)	405 (22%)
Diabetes (<i>definition 2</i>), n (%)	386 (21%)
Heart disease, n (%)	346 (19%)

SD: standard deviation; *definition 1*: hemoglobin A1C level ≥ 6.5% at last visit or the use of any medications to manage diabetes at initial or follow-up visits; *definition 2*: hemoglobin A1C level ≥ 7% at last visit or diabetes medication use at initial or follow-up visits.

Table 2. Reliability of self-reported hypertension, diabetes, and heart disease among individuals, before and after excluding the first consecutive negative self-reports of participants when they later consistently had positive self-reports.

Before exclusion	Hypertension	Diabetes	Heart disease
Unadjusted	0.959	0.983	0.948
Adjusted for sex, age, education, and ethnicity	0.968	0.987	0.951
After exclusion	Hypertension	Diabetes	Heart disease
Unadjusted	0.987	0.995	0.986
Adjusted for sex, age, education, and ethnicity	0.987	0.995	0.986

Table 3. Validity of self-reported against measured hypertension, diabetes and heart disease stratified by participants characteristics.

Variable	Group	Hypertension					
		Cohen's kappa	Sensitivity (%)	Specificity (%)	Underreported	Overreported	%agree
All		0.58 (0.53-0.63)	88.6 (86.9-90.1)	78.1 (73.0-82.7)	11.4 (9.9-13.1)	21.9 (17.3-27.0)	87.0
Age	65-80.9	0.56 (0.49-0.62)	85.6 (82.9-88.0)	79.0 (72.2-84.7)	14.4 (12.0-17.1)	21.0 (15.3-27.8)	84.3

RESEARCH IN CONTEXT (150)

Systematic Review: The authors reviewed the epidemiological literature on the use of questionnaires for cardiovascular and cerebrovascular risk factors. These vascular risk factors are important antecedents for heart disease, stroke, and dementia. However, the reliability and validity of self-reported vascular risk factors has not been widely investigated in studies of aging and dementia.

Interpretation: The findings here show that self-report of the most common vascular risk factors is reliable and valid. However, there are slight, but important differences by age, sex, education, and race/ethnic group in validity of these self-reported conditions when compared with direct measurements.

Future directions: This study provides confidence that ascertainment of vascular risk factors through self-report is reliable and valid. Establishing reliable and valid questionnaires across different race/ethnic groups, languages, educational levels, age, and sex is also critically important in the study of dementia.
