ABSTRACT

Dietary interventions constitute a means of untapped potential for the prevention and management of diseases including cardiovascular disease (CVD) and inflammatory disorders. The extent to which dietary modification can contribute to disease prevention and treatment however remains unclear. Here, we addressed the effects of a dietary pattern, involving periodic animal product restriction (APR), on markers of human health. We compared blood biomarkers, complete blood counts, anthropometric traits and blood pressure between two dietary states for a unique group of 200 individuals from Greece, who alternate between omnivory and APR, for religious reasons. We used linear mixed effects models to report changes in measured traits between dietary states. Short-term APR was linked to a reduction in levels of total and LDL cholesterol [both β=-0.3, p<0.0001], to a 72% decrease in CRP concentration [β=-1.3, p=0.001], to reduced platelet counts [β=-9.8, p<0.0001] and to a concurrent reduction in CVD risk (5.3% to 4.9%, p=0.02), shifting APR-practicing individuals from a high to a low-to-moderate risk group. Beneficial changes were recorded for markers of renal and liver function, with the exception of ALP [β=2.5, p<0.0001]. These changes were not detected in a control group of 211 continuously omnivorous individuals. Overall, short-term APR was linked to a biomarker profile associated with positive effects on health, suggesting that even modest dietary modifications can be harnessed towards disease prevention.

Keywords: dietary restriction, biomarkers, disease prevention, inflammation

Introduction

Dietary patterns that partially or wholly exclude animal products have been associated with a low risk of major chronic diseases, including cardiovascular disease, type 2 diabetes and inflammatory bowel disease [1-3]. Indeed, there is growing evidence that plant-based diets have the potential to act as powerful interventions for the prevention and treatment of a wide range of conditions [4] with cross-sectional and interventional studies linking them to beneficial effects on BMI, total and LDL cholesterol, blood glucose, CRP, serum urea, urinary creatinine and γ-GT [3,5-10]. Vegan diets in particular, which involve abstinence from all animal products, have been additionally associated with lower risk of cancer incidence, diabetes, diverticular disease, cataracts [3,9,10], but to a higher risk of bone fractures [9-11]. Emerging evidence also suggests an impact on the immune system [12,13] with vegan diets being linked to improvement of symptoms in rheumatoid arthritis patients [14]. Despite their positive impact on health, these diets can be too restrictive for practicing individuals, thus, individuals often choose to abstain only from some animal products or to reduce meat consumption. Consequently, there is a growing trend toward flexitarian approaches (flexible diets involving the consumption of a range of plant-based foods with limited consumption of animal products) which have been linked to health benefits including diabetes risk and blood pressure reduction [15]. This dietary shift is also recommended by the European Society of Cardiology (ESC) with its latest guidelines recommending the substitution of meat with plant foods for the improvement of cardiovascular health [16].

Given their substantial beneficial effects, it is important to gain a comprehensive understanding of how dietary patterns that restrict animal products affect markers of human health. To date, most studies involving large numbers of individuals are cross-sectional and while they build on existing knowledge, they do not allow for causal inference and usually report on a relatively limited number of outcomes or measurements. Important insight has been provided by meta-analyses of observational studies and randomised controlled trials (RCTs), but these studies suffer from limitations arising from the heterogeneity of primary studies analysed. Heterogeneity pertains to the variability in dietary patterns (e.g. vegan, vegetarian, flexitarian), to the health status of participants (e.g. healthy, obese, at-risk, patients), to the dietary intake of control groups (e.g. no dietary intervention, specific dietary interventions), to lack of adjustment for important confounders (e.g. sex, age, and BMI) and to the duration of the dietary intervention (a few weeks to several months). Typically, most studies involve interventions of over 12 weeks and thus do not map acute responses to dietary interventions, although some studies involve shorter interventions [12].

To address the gaps in our knowledge, we established FastBio (Fasting Biology), a follow-up study focusing on a unique subgroup of the Greek population that follows a lifelong dietary pattern involving periodic restriction of animal products [17]. These individuals alternate between omnivory and animal product restriction (APR), for religious reasons, in a highly structured manner. We explored effects of this dietary pattern on markers of human health and compared findings to those from a continuously omnivorous group from the general population.

Methods

Recruitment and selection of participants

The FastBio study was advertised during Autumn 2017 to the local communities of Thessaloniki, Greece through various means, including the press, radio, social media, and word of mouth. Candidate participants expressed their interest via telephone, email or via the project's website (www.fastbio.gr). Following screening of over 1,000 candidates through two interviews, 411 apparently healthy, unrelated individuals, who met FastBio selection criteria (Supplementary Text S1) were included in the study. Participants belonged to one of two groups, specified by their dietary habits: 200 individuals who follow a temporally structured dietary pattern of periodic restriction of animal products (periodically restricted, PR group) and 211 individuals who follow the diet of the general population (non-restricted group, NR group). PR individuals constitute a unique study group given their consistent and predictable adherence to a specific dietary pattern (Supplementary Text S2). Restriction is practiced for religious reasons, as specified by the Greek Orthodox Church and involves alternating between omnivory and restriction of animal products, including meat, fish, dairy products and eggs (but not molluscs and shellfish), for 180-200 days annually. This dietary pattern involves four extended periods of APR throughout the year, and on on Wednesdays and Fridays of each week (Supplementary Fig. S1). During periods of restriction, PR individuals also typically consume less alcohol. When not restricted, PR individuals follow an omnivorous type of diet. Only PR individuals who had practiced periodic APR for at least ten years were included in the FastBio study. Notably, very few participants were receiving dietary supplements (Supplementary Text S3). NR participants were continuously omnivorous individuals from the general population, who were not under any kind of special diet.

Collection of data, of biological material and measurement of traits

FastBio participants were invited to two scheduled appointments at the Interbalkan Hospital of Thessaloniki. The first appointment took place in October-November 2017 (Timepoint 1, T1) and covered a period where all PR individuals had been on an omnivorous diet (excluding

Wednesdays and Fridays) for a period of eight or nine weeks. The second appointment (Timepoint 2, T2) took place in March 2018, and covered a period during which PR individuals had abstained from meat, fish, dairy products and eggs for three to four weeks during the abstinence period prior to Easter (Lent). At T2, a recall rate of 95% was achieved, with 192 (out of 200) PR participants and 198 (out of 211) NR participants attending both appointments. All appointments were scheduled between 7:30-9:30 am to minimize circadian effects and were completed during a two-week window to minimize effects of seasonality [18]. The ethics committee of BSRC Alexander Fleming approved the study protocols, the study was performed in line with the principles of the Declaration of Helsinki, and all participants provided written informed consent.

For each participant, following overnight fasting, a blood sample was collected by a certified nurse and was taken for biomarker and complete blood count (CBC) testing at the InterBalkan Hospital facilities (cobas c 311 analyzer, Roche Diagnostics). We report results on 16 blood (serum) biomarker traits and 23 CBC traits (Supplementary Table S1). Biomarkers were grouped to allow for broad interpretation [5]: blood lipids (total cholesterol, LDL cholesterol, HDL cholesterol, triglycerides), glucose metabolism (glucose, insulin, HbA1c), renal function (urea, uric acid, creatinine), liver function (aspartate aminotransferase (AST), alanine aminotransferase (ALT), gamma-glutamyltransferase (γ-GT)), bone and liver function (alkaline phosphatase (ALP)), thyroid function (thyroid-stimulating hormone (TSH)), and inflammation (C-reactive protein (CRP)). Using glucose and insulin measurements, we calculated homeostatic model assessment (HOMA) indices to assess beta-cell function (HOMA-B) and insulin resistance (HOMA-IR) (Supplementary Text S4). Height was measured to the nearest 0.5 cm using a stadiometer. Body weight was measured with the use of a calibrated digital scale with an accuracy of ±100g. BMI was calculated as body weight divided by the square of height (kg/m^2). Systolic and diastolic blood pressure (SBP and DBP respectively) were measured using a traditional sphygmomanometer.

Statistical analysis

We performed multivariable regression analysis using linear mixed effects (lme) models with random effects ("nlme" R version 4.1.1) to report within-group changes in measured traits between T1 and T2, with T2 (restriction timepoint) as the reference timepoint (Supplementary Text S5). Between-group differences within each timepoint are also reported, with PR as the reference group (Supplementary Text S5). Tukey's correction was performed for all associations and P-values < 0.05 were considered statistically significant. Prior to statistical analysis, the

sampling distribution for each trait was investigated and eight non-normally distributed traits (triglycerides, glucose, insulin, creatinine, AST, ALT, γ-GT and CRP) were log-transformed prior to regression analyses. For CRP, 49 individuals (25 PR and 24 NR) with values suggesting acute inflammation (CRP>5 mg/L) were excluded from further analysis. All statistical analyses were performed using R software, version 4.1.1.

Blood biomarkers and CBC traits

We fitted lme models on measured traits with sex, age, and BMI as fixed confounders (Supplementary Text S6, Table S2) and included an interaction term between dietary group (PR or NR) and timepoint (T1 or T2) to conduct comparisons. We also corrected for medication use to account for effects on measured traits (Supplementary Text S7). Adjusting for smoking and alcohol consumption did not have an impact on our results (Supplementary Text S7). Individual heterogeneity was accounted for by including participant ID as a random intercept.

Anthropometric traits and blood pressure

We fitted lme models on weight and BMI as described above, but without adjustment for BMI. We also fitted lme models for SBP and DBP with the above covariates, adjusting additionally for smoking status, which is a known risk factor for hypertension [19]. Participants were defined as smokers and non-smokers (with past smokers and e-cigarette users also considered as non-smokers) based on NHS guidelines (https://www.nhs.uk/live-well/quit-smoking/using-e-cigarettes-to-stop-smoking/).

Calculation of 10-year CVD risk score

The 10-year CVD risk score was calculated for participants ≥ 40 years old, as specified by the ESC guidelines, through the SCORE2 risk calculators (https://u-prevent.com/calculators/ascvdScore). ESC defines four risk groups based on country-specific CVD mortality, with Greece belonging to the moderate risk group, therefore the moderate risk calculator was used [20]. The SCORE2 and SCORE2-OP algorithms were applied to individuals aged 40-69 years old and ≥ 70 years old respectively. The scores take into account age, sex, smoking status, SBP, total cholesterol and HDL cholesterol as predictors and are applicable to apparently healthy individuals with no previous CVD or type 2 diabetes mellitus. We calculated the score for 158 PR individuals (89 females and 69 males) and 122 NR individuals (65 females, 57 males) for both timepoints. A Wilcoxon signed-rank test was used to assess the change (%) in the CVD risk score between timepoints and a *P*-value < 0.05 was considered statistically significant.

Results

Study population characteristics

Table 1 and Supplementary Table S2 show the characteristics of FastBio participants at T1. Compared to NR individuals, PR were on average older and had higher BMI and blood pressure (Table 1). Both groups consisted of slightly more female participants, while most individuals were non-smokers (never smoked or stopped) with PR individuals being less likely to smoke. The vast majority were apparently healthy (according to self-reports) although a minority had underlying chronic conditions, including diabetes, arterial hypertension and hypothyroidism, for which treatment was being received (Supplementary Table S3). Mean values of blood biomarkers and CBC traits at both timepoints are summarised in Supplementary Table S1.

Table 1. Study population characteristics at timepoint 1 (T1) [a]

	PR (N=200)	**NR (N=211)**	**Total (N=411)**
Age (years)	51.5 ± 13.5	45.0 ± 13.1	48.1±13.6
Sex (female %)	108 (54.0)	116 (55.0)	224 (54.5)
BMI (kg/m^2)	28.4 ± 4.6	26.2 ± 4.4	27.3 ± 4.6
Smoking status (Yes %)	13 (6.5)	70 (33.2)	83 (20.2)
Blood pressure (mmHg)			
SBP	127±19.0	121±19.7	124±19.4
DBP	80±10.8	78±11.8	79±11.3

[a] Continuous variables were expressed as mean ± standard deviations and categorical variables as %.
BMI = Body Mass Index, SBP = Systolic Blood Pressure, DBP = Diastolic Blood Pressure

Within-group changes in measured traits between T1 and T2

Blood biomarkers

In the PR group, we report changes in nine out of the 16 blood biomarkers measured (Table 2, Fig. 1) including substantial reductions in total and LDL cholesterol, urea, creatinine, ALT, and γ-GT. Furthermore, we report a notable decrease in levels of CRP (72.8%, p = 0.001). A small decrease is also reported in levels of HDL cholesterol. Increased levels were only observed for ALP (Table 2). In NR individuals we report only small changes in levels of creatinine and γ-GT (Table 2, Fig. 1).

CBC traits

We report changes in 13 and 10 out of the 23 CBC traits measured, in the PR and NR groups respectively (Table 3, Fig.1) with both dietary groups displaying a reduction in total white blood (WBC) counts. Furthermore, both groups, display changes in lymphocyte %, monocyte %, neutrophils and neutrophil % (Table 3) while for red blood cell traits we report a decrease in

MCH, MCV, and RDW SD (Table 3, Fig.1). In the PR group only, we report an increase in

eosinophil %, and decreased levels of hemoglobin, haematocrit, MCHC, and platelets. In the

NR group only, we report a small increase in monocytes and red blood cells (RBC) (Table 3,

Fig.1).

Anthropometric traits and blood pressure

A very small decrease in BMI was observed in the PR group only, from T1 to T2. Additionally,

a small decrease in DBP was observed for both dietary groups (Table 4).

Figure 1: Changes in measured traits recorded from T1 to T2 for each dietary group. In PR individuals (red), short term-APR was associated with mostly beneficial changes in multiple markers of health, including prominent reductions in levels of total and LDL cholesterol and of CRP. Fewer changes, likely capturing seasonal effects on the immune system, were recorded for the NR group (blue).

10-year CVD risk score

Upon APR, the CVD risk score for PR individuals (mean age = 56.0 years old) decreased from 5.3% to 4.9% (p = 0.02) resulting in a shift of PR individuals from the high to the low-to-moderate risk group, according to the latest ESC guidelines [16]. No change in CVD risk score was detected for NR individuals (from 5.2% to 5.0%, p = 0.2).

Between-group differences of measured traits at T1 and T2

At T1, when both dietary groups were on an omnivorous diet, we report no differences in blood biomarker levels between PR and NR individuals (Table 2). At T2 (restriction timepoint), we report lower levels of total and LDL cholesterol, urea and creatinine for the PR group, but higher levels of ALP (Table 2). We also report differences for CBC traits with PR individuals displaying lower levels of eosinophils and eosinophil % at T1, and lower levels of WBC and neutrophils at T2 compared to the NR group (Table 3). No differences were observed in anthropometric or blood pressure traits between dietary groups.

Discussion

Principal findings

In the present study we find that short-term APR is linked to a substantial decrease in the levels of total and LDL cholesterol, to a 72.8% decrease in normal-range concentration of CRP, to improvements in markers of renal and liver function, and to a reduction of CVD risk (Fig. 2). Most changes were in a direction associated with positive effects on health, with the exception of ALP, a proxy of liver and bone health [21], which increased upon APR and may reflect negative effects of this dietary pattern on bone health. Given that this flexitarian type of diet is relatively easy to implement, further work is required to evaluate its long-term effects on human health, including its impact on liver fat accumulation [22], and its potential for lowering of risk for chronic diseases.

Figure 2: Effects of short-term APR on proxies of human health. A three-to-four week course of APR is associated with reduced levels of total and LDL cholesterol, reduced concentration of normal-range CRP and a reduction in the 10-year CVD risk.

Blood lipids

We report rapid reductions of both total and LDL cholesterol levels upon APR, which drive a
reduced risk for CVD risk following restriction, as measured by SCORE2. This reduction in
CVD risk shifts PR individuals from a high to a low-to-moderate risk CVD category. SCORE2
[20], an index based on age, sex, smoking habits, SBP, total cholesterol and HDL cholesterol, is a
widely accepted tool used by clinicians for the prediction of 10-year risk for fatal and non-fatal
CVD events. In the present study we find that CVD risk scores changed from 5.3% to 4.9% for
the PR group and from 5.2% to 5.0% for the NR group. Despite being only of slightly higher
magnitude, the change in risk score was significant only for the PR group. Notably, this group
is on average older and has a higher BMI (Table 1) compared to the NR group. Considering that
aging is a non-modifiable risk factor for CVD events [23] and that increasing BMI is one of the
leading risk factors for CVD [24], the documented shift of PR individuals to a lower CVD risk
category upon short-term APR is of key importance as it demonstrates the potential of moderate
lifestyle interventions to mitigate CVD risk.
Furthermore, while APR was linked to lower levels of total and LDL cholesterol, it was also
linked to a slight decrease of HDL cholesterol levels. This effect on blood lipids has been
reported previously [9,25] and may stem from the substantial reduction of animal fat intake. Given
the impact of dietary intake on CVD risk, incorporating dietary information in CVD prediction
models, in addition to the classical CVD risk factors, could improve robustness of patient
classification and of CVD risk prediction.

Despite the relatively short duration of APR in the present study, the reduction in total and LDL cholesterol reported (0.3 mmol/L) was larger or comparable to changes reported in meta-analyses of RCTs studying similar types of dietary interventions, including vegan diets of three times longer duration [6,7]. For example, in a meta-analysis of individuals at high risk of CVD, Rees et al. report reductions of 0.24 mmol/L and 0.22 mmol/L for total and LDL cholesterol respectively, after at least 12 weeks of a vegan diet [7]. Similarly, Selinger et al [9] report a decrease of 0.48 mmol/L in LDL cholesterol in a meta-analysis of healthy individuals following a vegan diet for at least 12 weeks. Meta-analyses for similar dietary interventions in individuals with overweight, diabetes or at high risk for CVD report reductions in levels of total and LDL cholesterol ranging from 0.07 to 0.24 mmol/L [6,9]. Through FastBio, we therefore unveil comparable effects on blood lipids through an intervention that is easy to apply and is of a shorter duration.

To put our finding in context, statin use lowers LDL cholesterol levels by an average of 1.8 mmol/L, reducing risk of ischemic heart disease (IHD) events by 60% and of stroke by 17% [26]. Although the effects reported in the present study are of lower magnitude, they are nevertheless rapid and substantial suggesting that APR can be applied in combination with lipid-lowering therapy as a preventive measure against CVD.

Markers of inflammation and immune system cells

Following APR, a 72.8% reduction was recorded for circulating, normal-range levels of CRP in PR individuals, suggesting a tempering effect of this diet on inflammation. Some evidence in the same direction is provided by meta-analysis of cross-sectional studies showing that permanent vegans have lower concentrations of CRP compared to omnivorous individuals [27].

Importantly, the design of the present study enabled us to capture likely seasonal effects on the immune system. From autumn (T1) to spring (T2) both dietary groups undergo changes in total WBC counts, lymphocyte %, monocyte %, neutrophil counts and neutrophil %, in line with findings from the UK Biobank [18] (with the exception of monocyte %). In addition to seasonal findings, we report higher levels of eosinophil % and lower levels of hemoglobin, hematocrit, MCHC and platelets in the PR group only. The decrease observed in platelets, which in addition to their role in haemostasis and thrombosis can initiate or modulate protective or adverse immune functions [28], is in line with findings from a smaller interventional study on 53 individuals who consumed a vegan diet for four weeks [12]. The same study reported that numbers of monocytes and neutrophils, but not lymphocytes, decreased upon animal product abstinence, with no changes reported for the dietary group following a meat-rich diet. Furthermore, a recent study on vegan versus ketogenic diets in humans [13] reported that neutrophils were the main

driver for the upregulation of pathways linked to innate immunity, following a two-week vegan diet.

Overall, the reduction in CRP levels uncovered in the present study is of key importance as translational research studies and clinical trials highlight the central role of inflammation in the development of atherosclerosis [29]. Although successful pharmacological approaches for the past 40 years were centred around LDL cholesterol lowering only, clinicians now have strong evidence that inhibition of inflammatory targets including CRP, IL-6 and IL-1β can protect against atherosclerosis [30]. An example of such a trial is CANTOS, which targeted IL-1β through an antibody resulting in reduction of major CVD events by 15-17% [30]. The inhibition of IL-1β was directly linked to the reduction in IL-6 and CRP. Therefore, elucidating the modulatory effect of dietary interventions on the immune system remains a largely untapped resource of enormous potential for the prevention and treatment of disease.

Renal, liver and bone health

Building on knowledge from cross-sectional studies [5], we report rapid reductions in levels of urea and creatinine associated with APR, likely reflecting decreased protein intake. We also observed a decrease in levels of ALT upon restriction, suggesting lower levels of fat deposition in the liver [31,32] and potentially protective effects against hepatic steatosis [33]. Furthermore, at T2, levels of γ-GT are reduced for both PR and NR groups, likely reflecting lower levels of alcohol consumption. Although this was expected for the PR group, lower γ-GT levels in the NR group may be a consequence of awareness bias following participation in the study at T1, and subsequent curbing of alcohol consumption. Notably, ALP levels increased upon APR suggesting possible negative effects on bone or liver health [21]. Large cross-sectional cohort studies have shown that permanent vegans have a higher risk of bone fractures [11]. We suggest that higher ALP levels may reflect negative effects of periodic APR on bone health, but further studies are needed to establish the magnitude of effect of this dietary pattern on bone health by using more representative tests such as quantification of bone mineral density (BMD), bone-specific ALP, C-terminal telopeptide (CTx) and parathyroid hormone [34].

Strengths and limitations

The key strength of the FastBio study is that it comprises a unique group of individuals who have followed a specific dietary pattern, in a consistent manner, for at least a decade. FastBio PR individuals therefore are highly homogeneous in the foodstuffs they abstain from, and we hypothesize that restriction from these products drives a large fraction of reported effects. Despite the enormous potential of dietary interventions to contribute to the prevention and

treatment of disease, attaining this level of homogeneity in dietary studies is challenging and adhering consistently to specific diets for prolonged periods of time can prove difficult, resulting in substantial heterogeneity in the dietary groups studied. Furthermore, in contrast to studies reporting on a few measurements, FastBio is one of the most comprehensive studies addressing the effects of APR on markers of health, reporting on 16 biomarker and 23 CBC traits, as well as on anthropometric and blood pressure traits. Importantly, the FastBio study enables us to disentangle effects driven by seasonality and given the sampling strategy applied, to minimise circadian effects on traits such as WBCs and CRP that are known to display significant daily variation [18].

A limitation of the FastBio study is that traits were measured at two distinct timepoints (approximately five months apart), but not immediately prior to initiation of restriction, meaning that we do not have typical baseline measurements. Prior to initiation of restriction however, PR individuals had undergone a period of omnivory that was similar in length to the period of omnivory prior to T1. This supports the idea that prior to restriction at T2, for the traits measured in the present study, the PR group had a similar biological profile to that measured at T1. Furthermore, most blood biomarkers measured are known to capture relatively acute dietary effects, meaning that with the present measurements we are underpowered to detect likely long-term effects of periodic restriction of animal products on markers of human health. Another limitation of our study is that we report on levels of inflammation through quantification of CRP levels instead of high-sensitivity CRP (hs-CRP), which is more commonly used to detect the risk for inflammatory conditions [35]. Finally, although we have adjusted for confounding factors to the best of our ability, some residual effects may persist in reported results.

Conclusions

Over the past decades flexible dietary patterns that are compatible with food variety, cultural traditions, and personal preferences are growing in popularity [36]. The combination of these elements can be found in flexitarian type of diets that are less restrictive and have a likely positive impact on human health[15]. The dietary pattern presented here constitutes such an approach and results in a biomarker profile compatible with positive effects on health and a reduction of CVD risk. Although further work is necessary to address potential negative effects on bone health and to evaluate long-term effects, harnessing flexitarian type of dietary interventions is a promising approach that can be applied for disease prevention, and that can inform on future public health dietary guidelines.

Figure 1: Changes in measured traits recorded from T1 to T2 for each dietary group. In PR individuals (red), short term-APR was associated with mostly beneficial changes in multiple markers of health, including prominent reductions in levels of total and LDL cholesterol and of CRP. Fewer changes, likely capturing seasonal effects on the immune system, were recorded for the NR group (blue).

Figure 2: Effects of short-term APR on proxies of human health. A three-to-four week course of APR is associated with reduced levels of total and LDL cholesterol, reduced concentration of normal-range CRP and a reduction in the 10-year CVD risk.
