ABSTRACT

Access to contraception is critical for limiting fertility. Yet, in South and Southeast Asia, access to these resources is often limited by spatial inequalities between rural and urban areas. Access to a motorcycle may empower women living in rural areas to attenuate these spatial inequalities, increase their educational attainment and participation in labor markets, and thereby facilitate a shift in fertility preferences. Concomitantly, motorcycle access may increase access to contraception for geographically isolated women who desire to limit fertility. We employ logistic regression models to examine associations with contraception use and unmet need for contraception for women living in rural vs. urban areas and for women with vs. without access to a motorcycle. Roughly 40 percent of women reported current use of contraception while another 21 percent indicated an unmet need for contraception. After adjusting for other variables, women with a motorcycle were more likely to report current contraception use (AOR = 1.55, 95% CI [1.50, 1.61]), modern contraception use (AOR = 1.60, 95% CI [1.54, 1.66]), and traditional contraception use (AOR = 1.49, 95% CI [1.41, 1.58]) compared to women who did not own a motorcycle. Women with a motorcycle were less likely to report an unmet need for contraception (AOR = 0.65, 95% CI [0.62, 0.68]) after adjusting for other variables. Our results are consistent with the premise that motorcycles facilitate contraception use among women living in resource-limited countries in South and Southeast Asia and thereby contribute to decreases in fertility. These relationships are contextualized by whether a woman lives in an urban or rural setting, and the number of children already present in their household; they are robust to controlling for household-level wealth and other factors that may mediate associations with contraception use.

Acknowledgement

Evaluating the economic, demographic, and social impacts of the mass influx of inexpensive motorcycles to limited-resource countries, especially in Southeast Asia, was the brainchild of the late Dr. Ralph B. Brown. Sadly, Dr. Brown is no longer with us. Former colleagues at Brigham Young University where he worked as Professor of Sociology have murmured against his continued listing as a co-author on manuscripts; even for manuscripts that he played a significant role in conceptualizing and contributing to their analysis and writing. To appease the murmuring voices, we have decided to no longer list Dr. Brown as last author on this and future manuscripts; however, we wish to express our deepest gratitude for his contributions, for the mentorship that he provided to many of us along our academic journeys, and for his unmitigated friendship. Ralph, you are dearly missed, hoser.

1 INTRODUCTION

Synthesizing themes in demography, sociology, and geography we argue and present evidence that

in the resource-limited countries of South and Southeast Asia, access to motorcycles facilitates

transitions to lower fertility through increasing use of contraception. The first of three core themes

in this research is the transition to low fertility and the prevalent use of contraception in resource-

limited countries (Barber and Axinn 2004; Hirschman 1994; Korinek et al. 2006; Morgan and

Hagewen 2006). The second theme, spatial inequality, addresses the classic question of social

stratification "who gets what?" by adding the context of "where" (Lobao et al. 2007). Finally, the

third theme considers the impact of physical mobility in attenuating spatial inequalities (Cooley

1894; Leinbach 2000; Rigg 2002), specifically investigating the impact of motorcycles as a

"distance demolishing technology" (Scott 2009: 11).

Building from the widely held understanding that increases in educational attainment and labor

market participation are associated with increased demand for limited fertility and that access to

contraception is critical for limiting fertility (Axinn and Barber 2001; Bongaarts 1978; Bongaarts

and Casterline 2018; Easterlin 1975; Hirschman 1994; Moursund and Kravdal 2003), we assert

that access to education, labor markets, and contraception is often limited in resource-limited

countries across spatial divides between rural and urban locations due to uneven development

(Gottdiener and Hutchison 2010; Korinek et al. 2006; Smith 2008). We further assert that "distance

demolishing technologies" (Scott 2009: 11); e.g., motorcycles in South and Southeast Asia, may

help isolated individuals access resources that are generally located in more urban or suburban

regions of resource-limited countries. Access to a motorcycle may help women living in rural areas

attenuate disadvantages resulting from spatial inequalities and increase their educational

attainment and participation in labor markets (Jayachandran 2021; Lobao et al. 2007); thereby

facilitating a shift in fertility preferences at the individual and family level. Concomitantly, access

to a motorcycle may also increase access to and use of contraception for spatially isolated women

who desire to limit fertility and thereby contribute to future declines in fertility (Bongaarts and

Casterline 2018). We anticipate that examining these associations through the lens of a life course

perspective for contraception use (Rindfuss et al. 1996) should enhance our overall understanding.

To test these assertions, we examine the extent to which residence in an urban versus a rural

location is associated with the use of contraception for female respondents in Cambodia, Indonesia,

Nepal, the Philippines, and Timor-Leste. We further analyze the extent to which motorcycle

ownership is associated with contraception use and evaluate effect modification between

motorcycle ownership, urban vs. rural residence, and the number of living children. These

relationships are evaluated while adjusting for a suite of factors commonly associated with

contraception use and/or fertility. Our results suggest that rural residence is negatively associated

with contraception use, motorcycle ownership is positively associated with contraception use, and

the association between motorcycle ownership and contraception use is stronger in rural areas

compared to urban.

BACKGROUND

The demographic transition to low fertility and the prevalent use of birth control is one of the most

thoroughly researched subjects in demography (Axinn and Yabiku 2001). Given the findings that

fertility is a primary indicator of personal autonomy and social mobility (Dharmalingam and

Morgan 1996; Docquier 2004; Ekert-Jaffe and Stier 2009; Korinek et al. 2006; Kravdal 1994), the

options and consequences of fertility are also central topics in social and economic development

studies (Docquier 2004; Ekert-Jaffe and Stier 2009), with scholars endeavoring to create

theoretical frameworks that explain changes in fertility in resource-limited countries (Korinek et

al. 2006). However, the pursuit of fertility frameworks, particularly in resource-limited countries,

is complex and debate continues. Extensive reviews of the fertility literature are already available

(Hirschman 1994; Morgan and Hagewen 2006; Upadhyay et al. 2014); thus, only a brief review

and synthesis is provided below.

The original theoretical framework used to explain fertility transitions came from Demographic

Transition Theory (DTT), which posited that changes in fertility occur as a result of structural

changes in society tied to modernization; e.g. urbanization, industrialization, increased education,

and reduced infant and child mortality (Davis 1963; Notestein 1945; 1953). However, DTT's poor

performance in anticipating fertility declines lead to substantial revisions and elaborations (Morgan

and Hagewen 2006), not to mention critiques (Coale 1973). Subsequent research, in particular that

of the European Fertility Project, offered an alternative explanation that focused on cultural

settings, the diffusion of new ideas and norms, and social interactions as key components leading

to changes in fertility (Bongaarts and Watkins 1996; Coale and Watkins 1986; Knodel and Walle

1979). Similar arguments are posited in more recent research evaluating the impact of mass media

in facilitating the rapid diffusion of new norms and values concerning fertility (Barber and Axinn

2004). However, structural explanations of fertility change were revisited with economic-based

arguments asserting that economic development results in a tradeoff between "quantity" and

"quality" in raising children (Barro and Becker 1989; Becker 1960; Becker and Lewis 1973;

Easterlin 1975). In essence, economic well-being shifts parents from seeking an increase in the

number of children for some immediate economic benefit to seeking to raise fewer but higher

quality children for future economic benefit. Such arguments are echoed to a degree in Caldwell's

work regarding wealth flows (Caldwell 1982). More recently, studies reinvestigating structural

explanations for fertility changes have highlighted the importance of social changes that increase

access to education and labor market participation and thereby increase the opportunity costs of

fertility (Axinn and Barber 2001; Brewster and Rindfuss 2000; Ekert-Jaffe 1986; Ekert-Jaffe and

Stier 2009; Hakim 2003; Knodel et al. 1984; Spain and Bianchi 1996). Addressing the wide variety

of theoretical frameworks, Hirschman (1994) and Morgan and Hagewen (2006) concur that the

various frameworks are not necessarily mutually exclusive and that reality likely resembles a

synthesis of these frameworks rather than a competition (Hirschman 1994: 222).

Apart from the role of social and economic structures and cultural ideals and norms, more proximal

causes (e.g., contraception use) are important factors influencing changes in fertility (Bongaarts

1978; Easterlin 1975; Feyisetan and Casterline 2000; Hirschman 1994; Morgan and Hagewen

2006; Phillips et al. 1988; Rindfuss et al. 1996). While Hirschman (1994) acknowledges that

fertility limitation occurred prior to modern modes of contraception, attributable in part to the use

of traditional contraceptive methods, evidence exists that recent family planning programs

(Phillips et al. 1988) and access to modern contraception (Bongaarts 1978; Moursund and Kravdal

2003; Townsend et al. 2011) help facilitate fertility decline. Furthermore, while the diffusion of

information concerning new fertility norms and contraception options may increase demand for

contraception, Feyisetan and Casterline (2000) find evidence that the available supply of

contraception does not always meet demand. Indeed, the unmet need for contraception is

continually reported by women globally, but especially by those living in many low- and middle-

income countries (Anik et al. 2022; Bongaarts and Bruce 1995; Feyisetan and Casterline 2000;

Sitruk-Ware 2006; Townsend et al. 2011). A recent study using Demographic and Health survey

data from 32 resourcelimited countries estimated that approximately 24 percent of women

experience an unmet need for contraception (Anik et al. 2022) and evidence suggests that unmet

need is greatest for those living in absolute poverty (Anik et al. 2022; Gakidou and Vayena 2007).

This gap in unmet need is concerning, as it exists despite progress in increasing access to a variety

of health products for individuals and families living in low- and middle-income countries (Sitruk-

Ware et al. 2013; Townsend et al. 2011). To help explain in part the continuing gap in unmet need

for contraception, we assert that spatial inequalities between and within countries, especially

resource-limited countries, lead to disparities in access to and use of contraception.

Spatial Inequality vs. Physical Mobility

Throughout the different fertility frameworks is the notion that the transition to low fertility and

the prevalent use of birth control is mediated by differential access to scarce resources. Whether

these resources are structural (e.g., access to contraception, labor markets, and educational

opportunities) or ideational (e.g., access to mass media and broader, culturally diverse social

networks), the critical link is that access to scarce resources is often limited by one's relative spatial

proximity to them (Agyei and Migadde 1995; Barber 2004; Barber and Axinn 2004; Jayachandran

2021; Leinbach 2000; Pebley and Sastry 2004; Townsend et al. 2011; Zakharenko 2010).

Accordingly, inequality in the spatial distribution of resources is likely to lead to inequalities in

access to these resources.

In the resource-limited countries of Asia and Southeast Asia, a stark contrast in spatial inequality

(Lobao et al. 2007) remains between rural and urban locations in terms of social and economic

development (Korinek et al. 2006; Rigg 2002). In such settings, geographic location vis-a-vis a

developed labor market or school affects an individual's access to employment and education

opportunities (Baschieri and Falkingham 2009; Korinek et al. 2006; Leinbach 2000). Similarly,

access to sources of mass media (Barber and Axinn 2004), and outside cultural influences are

mitigated by proximity to locations with these resources (Barber 2004). Consequently, women

located in relatively isolated, rural areas as compared to women located in more urban or suburban

locations, will generally have less access to these resources. They are also more likely to lack the

resources needed to bridge the disadvantages associated with physical isolation than their less

isolated counterparts (Attan´e 2002; Korinek et al. 2006; 2005; Leinbach 1983; Pebley and Sastry

2004; Rigg 2002).

Conversely, increased physical mobility empowers individuals and groups to transcend spatial

inequalities (Lobao et al. 2007) and increase access to scarce resources (Leinbach 2000; Rigg

2002). In urban and rural locations of resource-limited nations, physical mobility has the potential

to increase access to scarce resources such as education and occupational opportunities

(Jayachandran 2021; Leinbach 2000; Rigg 2002) as well as facilitate the diffusion of new ideas

and culture (Lawson and Borgerhoff Mulder 2016; Leinbach 2000; Rigg 2002); thereby acting as

an agent of development (Cooley 1894; De Koninck 2000; Kunstadter 2000; Leinbach 2000; Owen

1987; Rigg 2002). This critical role is augmented by access to owner-operated transportation or

transportation services that are affordable and reliable. Individuals with access to roads and

vehicles to transport them are able to access options that otherwise would not be possible (Leinbach

2000).

In as much as improved physical mobility may empower isolated individuals to access options and

opportunities that were previously unattainable, it is also possible that such improvements facilitate

the creation of opportunity costs to fertility through increasing an individual's access to education

and employment as well as improve access to contraception to control fertility. Accordingly, a

necessary next step in explaining changes in fertility in resource-limited countries is to examine

what types of interventions, technologies, and other mechanisms may help more geographically

and socially isolated rural women overcome their disadvantaged position in accessing resources

associated with declines in fertility that are generally located in more urban or suburban regions of

resource-limited countries. One increasingly prevalent technology in the resource-limited

countries of South and Southeast Asia that has yet to be examined for its potential to decrease the

isolation of rural women is inexpensive motorcycles.

Motorcycles as Distance Demolishing Technologies

Sometimes even the simplest of technological shifts can become the "engines" of social and

economic change (Cooley 1894; Lenski 1984; Muir 2012; 2018; Sanders et al. 2018). Beginning

in the mid-1990s, many Southeast Asian countries experienced dramatic increases in the number

and availability of inexpensive motorcycles, thus transitioning their respective populations from

pedestrian economies with a limited range of physical mobility to economies balanced on two

motorized wheels and based on increased mobility. In Indonesia for example, between 1987 and

2009, the number of motorcycles increased from 5.5 million to approximately 52.4 million over

this 22-year span with the most dramatic period of growth occurring from 1990 to 2009 at which

time the number of registered motorcycles increased by approximately 893 percent (Badan Pusat

Statistik 2011b; Badan Pusat Statistik 2011a). During the same approximate period, the total

amount of asphalted roads in Indonesia increased by approximately 52,000 kilometers (Badan

Pusat Statistik 2011b; Badan Pusat Statistik 2011a). These changes took place while the Indonesian

population increased by only 15 percent. Similar trends occurred in Vietnam, where, since 1990

motorcycles have increased by 1000 percent while the population increased by only 24 percent

(Hsu et al. 2007: 15). In 2003, 95 percent of all registered vehicles in Vietnam were motorcycles

(Hsu et al. 2007). Today, despite the increasing prevalence of automobile ownership, and with a

few exceptions (e.g., Malaysia, Brunei, and Singapore), motorcycles represent the primary means

of personal transportation for both rural and urban populations throughout Southeast Asia.

With access to one or more motorcycles in a household, members in that household become more

geographically mobile, which potentially increases access to jobs, mass media, and educational

opportunities. Furthermore, within the context of urban/rural dynamics, increased access to

transportation is associated with changes in household organization such that "genders and

generations renegotiate their respective roles" (Leinbach 2000: 5). Accordingly, increased physical

mobility should create significant shifts in social mobility, especially for young women, by shifting

their opportunity costs at the individual and household level from money "savers" to income

"producers" (Leinbach 2000).

Traditionally young women from rural regions in resource-limited countries are engaged in

"secondary" economic activities (e.g., planting and caring for a garden, watching livestock, etc.)

that save the household money versus making money (Cloud and Garrett 1996). Yet, given the

opportunity, rural households or resource-limited households prefer to have their members make

money (McMichael 2011; Morgan and Hagewen 2006) through engaging in "primary" economic

activities versus money-saving activities. This is true not only for men, but also for women as rural

families often propel female household members into employment opportunities as such

opportunities are viewed as a family duty or necessary source of income (McMichael 2011: 92).

Despite this preference, transportation costs and the lack of transportation infrastructure have been,

for many rural households in the resourcelimited world, a prohibiting factor (Jayachandran 2021;

Leinbach 1983; Olsson 2009; Replogle 1991; Rigg 2002). Consequently, young women tend to

stay at home while their male siblings leave to pursue incomes (Cloud and Garrett 1996;

Jayachandran 2021). When secondary economic activities prevail in rural households, higher

fertility is at worst inconsequential for the households' economic strategies and may in fact be

beneficial by providing more domestic labor for localized money-saving activities (Knodel et al.

1984; Morgan and Hagewen 2006). Furthermore, in resource-limited settings, children are often

viewed as additional potential laborers capable of increasing the flow of economic resources to the

household head (Caldwell 1982; Morgan and Hagewen 2006). Under such conditions higher

fertility is likely.

Access to relatively inexpensive motorcycles should alter the conditions favoring higher fertility

by influencing the economic strategies of individuals and households by decreasing transportation

costs, increasing access to labor markets, and thereby increasing opportunity costs of fertility, a

(Leinbach 2000). Under such a scenario, women and/or households may revise their economic

strategies to view women as potential money-generators in the shortterm, and even in the long-

term if they can access additional educational opportunities as a gateway to long-term career

opportunities. Early and frequent pregnancies in these conditions would constitute a major

disruption to individual and household economic strategies as the potential to earn an income is

more feasible. Moreover, increased physical mobility should empower women to reach broader

economic markets and thereby increase their access to contraception. Thus, access to motorcycles

should be associated with increased use of contraception as a means of addressing shifts in desired

fertility. However, these mechanisms likely function in tandem with more general life course

events.

Fertility and the Life Course

The life course perspective asserts that individuals face different challenges and desires depending

upon where they are in their life's journey and that earlier decisions or life events affect subsequent

decisions and life events. As such, an individual's age is a key indicator of a variety of life outcomes

and fertility is a prime example (Rindfuss et al. 1996). Young women typically enter menarche

somewhere between ages 11 to 15 and transition to menopause sometime around year 50, granted

that there are variations across times and locations (Zacharias and Wurtman 1969; Stanford et al.

1987). Within this time period, fecundity has a curvilinear relationship with age, first increasing in

an individual's late teens and early twenties, typically peaking in their early 30s, and then gradually

declining as they approach menopause (Homan et al. 2007). By necessity, fertility decisions and

experiences occur within these limits. In addition, evidence suggests that women with high parity

are more likely to limit future fertility through the use of contraception (Amin et al. 1987). We

anticipate that interventions to help women increase their access to and use of contraception will

be strongly influenced by these underlying patterns–Rindfuss et al. (1996) find that there are three

stages in the reproductive life course relevant to contraception use; i.e., early years, where

contraception is used to delay first births and control the tempo of fertility; mid-career, where

decisions are made whether or not to seep sterilization; and a final stage in which decisions revolve

around when to stop using contraception if not previously sterilized. With this in mind, we posit

that the impact of access to a motorcycle on contraception use is likely to change as a woman

traverses her life course.

Summary

We have introduced fertility change, spatial inequality, and physical mobility as central themes in

this article. Arguing in agreement with the established understanding that access to resources such

as education, labor markets, and contraception is critical for transitions to low fertility, we have

further argued that access to these resources is often limited in resourcelimited countries due to

spatial inequalities. However, we have proposed that motorcycles, which constitute a primary

"distance demolishing technology" (Scott 2009: 11) in South and Southeast Asia, may help isolated

individuals living in these regions increase their access to these resources and thus facilitate

transitions to low fertility across spatial divides through increasing the use of contraception. We

examine these propositions by examining the extent to which access to a motorcycle juxtapose

residence in a rural versus an urban location is associated with the use of contraception for female

respondents in Cambodia, Indonesia, Nepal, the Philippines, and Timor-Leste.

With the extant literature in mind, we developed the following research questions to guide our

investigation:

1. To what extent is access to a motorcycle associated with an increased probability of

contraception use?

2. To what extent and in what direction is residence in a rural versus an urban location

associated with the probability of contraception use?

3. Does an interaction effect exist between motorcycle access and rural versus urban residence,

such that the impact of access to a motorcycle in more pronounced in rural versus urban

locations?

METHODS AND MATERIALS

To answer these questions, we use data from the Demographic and Health Surveys (DHS):

Cambodia (CDHS 2005, 2010, 2014, and 2021), Indonesia (IDHS 2007, 2012, and 2017), Nepal

(NDHS 2006, 2011, and 2016), the Philippines (PDHS 2008, 2013, and 2017), and Timor-Leste

(TLDHS 2009 and 2016). Data from Bangladesh and Myanmar were also included in preliminary

analyses, but did not include all of the desired variables for the complete models (results that

included these data were comparable across similar models). DHS data are nationally

representative samples of female respondents from each respective country. Data were obtained

through face-to-face survey interviews conducted with women between the ages of 15 and 49 using

a formal survey instrument by trained interviewers. The DHS typically uses two-stage stratified

cluster sampling to collect nationally representative samples, which have been divided into

sampling domains. In the first stage, clusters, or enumeration areas (EAs), that represent the entire

country are randomly selected from the sampling frame using estimates of probability proportional

to cluster size (PPS). The second stage then involves the systematic sampling of households listed

in each cluster or EA. Given the focus of this study on current contraception use, we selected

women from the original sample who were not currently pregnant at the time of their interview

and who were not sterilized.

Measures

Analyses included in this research evaluate the relationships between key variables of interest and

control variables with the outcome variables contraception use, modern contraception use,

traditional contraception use, and unmet need. Contraception use was coded into a dichotomous

variable with 0 = no current use of contraception or current use of folklore contraception (e.g.,

spiritual or mystical methods) and 1 = current use of traditional contraception (e.g., withdrawal)

or current use of modern contraception (e.g., a condom, pill, or injection.). Two additional variables

were created to isolate and distinguish between modern and traditional contraception use, with

either category set to 1 and 0 = no current use of contraception or current use of folklore

contraception (an alternative coding that only included no current use of contraception as the

reference category was also analyzed; the results were not substantively different from the results

based on the combined reference group). A final outcome variable was created to represent an

unmet need for contraception, which was coded as 0 = using contraception for birth spacing or

limiting and 1 = unmet need for birth spacing or limiting.

A key indicator of interest in this study is area of residence, as it often mediates access to scarce

resources. In order to analyze the impact of spatial inequality, analyses included the variable

residence, which was a dichotomous variable coded as 0 = rural, 1 = urban. Juxtapose the potential

impact of place on contraception use, access to a motorcycle was measured based on household

ownership of a motorcycle, which was measured as a dichotomous variable coded as 0 = No, 1 =

Yes. Additional right-hand-sided variables, representing established indicators of fertility, were

included as control variables in our models. Demographic variables included age, living children,

and country of residence. Age was coded as an ordinal variable with standard 5-year age categories

from 15 to 49 years. Living children was the respondent's total number of living children, coded

as an ordinal variable with 0, 1, 2, and 3 plus children. Country was included as a categorical factor

variable indicating a respondent's country of residence (1 = Indonesia (reference), 2 = Cambodia,

3 = Nepal, 4 = Philippines, and 5 = Timor-Leste). Socioeconomic status was measured by

respondent's occupation, coded as a categorical factor variable (1 = none (reference), 2 =

professional, 3 = agricultural, 4 = subsistence, and 5 = manual labor), and by the household's

relative wealth status as indicated by the DHS wealth index (coded as 1 = poorest (reference), 2 =

poorer, 3 = middle, 4 = richer, 5 = richest). Educational/ideational control variables include

education and TV use. Education was coded as an ordinal variable where 1 = no education

(reference), 2 = incomplete primary, 3 = complete primary, 4 = incomplete secondary, 5 = complete

secondary, and 6 = higher. TV use represented the frequency that a respondent reported watching

TV (coded as 0 = none, 1 = less than once a week, 2 = at least once a week). Access variables

included health clinic visit and family planning visit, each coded as dichotomous variables (0 =

no, 1 = yes) for whether a respondent had visited a clinic or received a visit from a family planning

professional within the past year. Also included were variables representing whether or not money

or distance represented substantial barriers to accessing health care, each was coded as a

dichotomous variable with 0 = No, 1 = Yes.

Analytic Strategy

Statistical analyses were performed using STATA version 15.1. We formally incorporated the

DHS's complex sample design using the "survey" package and by including the "svy" command

in our logistic regression analyses. We used a combination of unadjusted and adjusted logistic

regression models to explore the relationship between our outcome variables and key independent

variables. Preliminary models included a baseline model, that evaluated unadjusted relationships

between our outcome and key independent variables, as well as pathway-specific models that

adjusted for related control variables (results for pathway specific models are available upon

request). A fully adjusted model was estimated to assess associations between motorcycle

ownership and residence with outcome variables, net the effects of all control variables. A final

model was estimated that included interaction terms between motorcycle ownership, residence,

and the number of living children. Results from the interaction model are presented as predicted

probabilities (see Figure 1).

RESULTS

Roughly 60 percent of women reported living in rural areas and 47 percent reported household

ownership of a motorcycle (see Tables 1-2). Women's age was distributed relatively evenly with

most age categories representing between 14 to 17 percent of respondents. Approximately 70

percent or women had at least one living child. About 13 percent of women had no education,

another 60 percent had less than a secondary education, and 28 percent had a secondary education

or higher. About half of the women reported working in a professional occupation or in agriculture,

and a little less than 40 percent reported not having an occupation. Less than 15 percent of women

reported having a recent visit from a family planning professional, but almost 43 percent had

visited a health clinic in the past year. Money was reported as a substantial barrier to accessing

health care by 40 percent of women and distance was reported by 29 percent.

Table 1: Descriptive Statistics by Outcome Indicator

	Contraception Use			Modern Contraception			Traditional Contraception			Unmet Need		
	No	Yes	Total	No	Yes	Total	No	Yes	Total	No	Yes	Total

Almost 40 percent of women reported current use of traditional or modern contraception while

another 21 percent indicated an unmet need for contraception. Associations with contraception use

are reported as adjusted odds ratios (AOR). After adjusting for other factors commonly associated

with contraception use, women with a motorcycle were more likely to report current contraception

use (AOR = 1.55, 95% CI [1.50, 1.61]), modern contraception use (AOR = 1.60, 95% CI [1.54,

1.66]), and traditional contraception use (AOR = 1.49, 95% CI [1.41, 1.58]) compared to women

who did not own a motorcycle (see Table 2). Women with a motorcycle were less likely to report

an unmet need for contraception (AOR = 0.65, 95% CI [0.62, 0.68]) after adjusting for other

variables. Women living in an urban area were more likely to report current contraception use

(AOR = 1.05, 95% CI [1.01, 1.09]) and traditional contraception use (AOR = 1.34, 95% CI [1.26,

1.43]) compared to women living in a rural area. Urban vs. rural residence was negatively

associated with unmet need for contraception (AOR = 0.90, 95% CI [0.85, 0.95]).

Women's age presented a curvilinear association with contraception use, first increasing in strength

with a positive association with contraception use, modern contraception use, and traditional

contraception use that peaked in strength between ages 20 - 24 and declined thereafter. A similar,

but inverse association, was observed between age and unmet need for contraption. Education was

positively associated with contraception use; for example, women who had completed secondary

education were more likely to report contraception use compared to women with no education

(AOR = 1.60, 95% CI [1.50, 1.71]). Education was inversely associated with an unmet need for

contraception; for example, women who had completed primary education were less likely to

report an unmet need for contraception compared to women with no education (AOR = 0.82, 95%

CI [0.76, 0.88]). Women who had visited a health clinic in the past year were more likely to report

contraception use compared to women who had not (AOR = 1.33, 95% CI [1.29, 1.37]); those who

reported a visit from a family planning professional in the past year were also more likely to report

contraception use compared to women who had not (AOR = 1.18, 95% CI [1.13, 1.23]). Having

reported money or distance as barriers to accessing health care were both negatively associated

with contraception use and positively associated with unmet need for contraception. Compared to

women living in Indonesia, women from other countries were less likely to report contraception

use and more likely to report an unmet need for contraception. For example, women from Timor-

Leste were less likely to report modern contraception use compared to women from Indonesia

(AOR = 0.20, 95% CI [0.18, 0.21.]). Finally, having a larger number of living children was strongly

associated with contraception use and inversely related to unmet need for contraception.

Given the strength of the association between the number of living children and contraception use,

a three-way interaction model was estimated to evaluate associations between motorcycle

ownership in the context of rural vs. urban areas, but also evaluate how these interactive

associations may vary depending upon the number of living children that a woman reported.

Results from this interaction model (fully adjusted for other control variables) were used to

generate predicted probabilities of contraception use, modern contraception use, traditional

contraception use, and unmet need for contraception; these predicted probabilities are visualized

in Figure 1. The probability of contraception use, particularly modern contraception use, was

higher for women who had at least one living child and who also owned a motorcycle. This pattern

of association was strongest for women living in rural areas. A moderate increase in probability of

traditional contraception use was found for women in both rural and urban areas if they had 2 or

more living children. Finally, motorcycle ownership was consistently associated with a lower

probability of reporting an unmet need for contraception by women living in a rural area regardless

of the number of living children that they reported. The same association is only seen for women

with 2 or more children who lived in urban areas.

Motorcycle Ownership   No   Yes

Figure 1. Predicted Probability of Contraception Use, Modern Contraception Use, Traditional
Contraception Use, and Unmet Need. Estimated by a three-way interaction between Motorcycle Ownership,
Residence, and Number of Living Children. Figures were created in R with the ggplot2 package.

DISCUSSION

Our results are consistent with the premise that motorcycles facilitate contraception use among women living in resource-limited countries in South and Southeast Asia and thereby contribute to decreases in fertility. This relationship is contextualized by whether a woman lives in an urban or rural setting and the number of children already present in their household; i.e., the observed associations between motorcycle ownership and various indicators of contraception use are strongest in rural locations and increase in magnitude with increases in the number of living children. These relationships are generally robust to adjusting for additional control variables; however, in urban areas, the degree to which motorcycles are associated with contraception use diminishes after accounting for other factors. It's noteworthy to highlight that contraception use appears to have a curvilinear relationship with women's age as its use declines as women age regardless of residence location, access to a motorcycle, or the number of children present in the household, supporting the premise that a life course perspective adds clarity to patterns of contraception use over time.

In proposing that motorcycle access is associated with an increased probability of contraception use and thereby negatively associated with fertility, we presented an argument that motorcycles create opportunity costs to fertility through increasing an individual's ability to access scarce resources such as education and labor market opportunities as well as facilitating the diffusion of new ideas and information-particularly in circumstances in which such opportunities are located beyond an individual's local community. Our results are consistent with these pathways functioning as potential mechanisms–including variables related to these pathways attenuated the strength of the association between motorcycles and contraception, but did not eliminate it. Importantly, our results are robust to controlling for household-level wealth. This suggests that motorcycle access functions beyond that of a proxy for household- or individual-level economic privilege. We further predicted that spatial inequalities associated with rural residence will negatively affect contraception use.

Results are consistent with this hypothesis–the relationship between rural residence and
contraception use was negative and generally robust to adjusting for additional variables. However,
the relationship between rural residence and contraception use does diminish after controlling for
indicators of socioeconomic status, education, and/or employment, suggesting that differences in
wealth, education, and employment account for part of this relationship. This is consistent with the
hypothesis that a distinguishing characteristic of rural vs. urban residence is that of spatial
inequality. It is of interest, however, that while the rural penalty diminishes, motorcycle ownership
remained a powerful indicator of increased probability of contraception use even after adjusting
for these control variables.

While the results support our premise concerning the relationship between contraception use
and access to a motorcycle, there are limitations. The largest limitation is the power of our data.
While DHS data is well adapted for cross-country comparison as it is collected in different
countries using comparable instruments, this data is cross-sectional at the individual level and thus
poses limitations for time-sensitive analyses of relationships between variables. This limits the
power of our models in testing causal mechanisms; thus, while we argue with confidence that the
models represent relationships of association, we are limited in our ability to argue for relationships
of causality. In addition, not all of the indicators included were ideal for the concepts we wanted
to control for, rather, they were the best approximation available. Future research should further
explore these relationships using longitudinal data with more precise indicators to address these
limitations, even if such data is available for only specific countries. Despite these limitations, we
believe that these analyses were conducted with the best data available for cross-country analysis
of trends in several of the resource-limited countries of Southeast Asia.

The innovative contribution of the research presented in this article is the synthesis of several
premises in making the argument that motorcycles potentially facilitate fertility transitions in
resource-limited countries through increasing access to knowledge, labor markets and
contraception. Individually, these core premises are not novel. What is novel, is the synthesis of
these ideas in arguing that a previously neglected technology, a motorcycle in South or Southeast

Asia, has the ability to help disadvantaged women living in rural regions cross spatial divides and

thereby increase their probability of using contraception and gain increased control over their

fertility. As such, it joins the list of other "Distance Demolishing Technologies" (Scott 2009) such

as cell phones and the internet that help individuals and their communities to overcome social and

economic isolation. We anticipate that these technologies help individuals overcome isolation

beyond the rural/urban divide. Furthermore, in as much as these technologies empower individuals

to overcome social and geographic isolation, they likely function as indicators of social mobility,

individual autonomy, and may even influence individuals' experience of community. Research

examining these would endeavor to answer the call for research investigating "innovative and

infrequently used measures" to understand women's empowerment (Upadhyay et al. 2014).
