Abstract

Understanding the complex causal relationships among major clinical outcomes and the causal interplay among multiple organs remains a significant challenge. By using imaging phenotypes, we can characterize the functional and structural architecture of major human organs. Mendelian randomization (MR) provides a valuable framework for inferring causality by leveraging genetic variants as instrumental variables. In this study, we conducted a systematic multi-organ MR analysis involving 402 imaging traits and 372 clinical outcomes. Our analysis revealed 184 genetic causal links for 58 diseases and 56 imaging traits across various organs, tissues, and systems, including the brain, heart, liver, kidney, lung, pancreas, spleen, adipose tissue, and skeletal system. We identified intra-organ causal connections, such as the bidirectional genetic links between Alzheimer's disease and brain function, as well as inter-organ causal effects, such as the impact of heart diseases on brain health. Metabolic disorders, such as diabetes, exhibited causal effects across multiple organs. These findings shed light on the genetic causal links spanning multiple organs, providing insights into the intricate relationships between organ functions and clinical outcomes.

Keywords: Abdominal MRI; Brain MRI; Cardiovascular MRI; Clinical outcomes; FinnGen; GWAS; Mendelian randomization; Skeleton DXA; UK Biobank.

Medical imaging techniques such as magnetic resonance imaging (MRI) provide important information about the structure and function of many human organs, such as the brain, heart, liver, and kidney. Their derived imaging traits have found widespread use in both clinical research and practical applications. For example, structural and functional imaging traits extracted from brain MRIs have consistently revealed abnormalities associated with Alzheimer's disease, particularly within the hippocampal region[1]. Cardiovascular MRI (CMR) provides quantitative data regarding ventricular function, cardiovascular structure, and myocardial perfusion, all of which are intricately linked to cardiovascular diseases[2]. Furthermore, skeletal dual-energy X-ray absorptiometry (DXA) aids in identifying novel genetic variants that influence the human skeletal structure, thereby revealing significant evolutionary trends in human anatomical changes leading to pathogenesis[3]. Several large-scale organ imaging datasets (on the scale of over 10,000 participants) have recently been made publicly available, revealing details about human organ structure and function[4-8]. A large number of complex traits and clinical outcomes have been found to associate with organ imaging traits in these population-based studies[9,10].

Despite these advances, inherent limitations in observational data pose challenges in definitively establishing causal relationships between imaging traits and clinical outcomes, as well as in gaining a comprehensive understanding of the causal interplay across various organs[11]. Mendelian randomization (MR) uses genetic variants as instrumental variables to infer causality from observational data[12,13]. Operating under certain assumptions regarding genetic, exposure, and outcome variables, MR is an epidemiological tool to uncover causal relationships between exposure and outcome variables, while controlling for confounding factors. Both family and population-based studies have demonstrated that numerous imaging traits and complex diseases are profoundly influenced by genetics. Hundreds of associated genetic loci have been pinpointed in large-scale genome-wide association studies (GWAS)[3,8,14-28]. Using these GWAS summary-level data (summary statistics), MR methods can unveil causal relationships between imaging measurements and clinical outcomes. Numerous recent MR studies have explored the genetic causality of imaging traits[11,29-34]. However, a common limitation of these MR studies is their focus on a single organ (or imaging modality) and/or a single disease, or diseases in a specific domain, such as brain imaging and psychiatric disorders[29]. It is crucial to note, however,

that many diseases act as the causes and/or consequences of functional and structural changes in various organs of the human body[35,36]. Cross-organ analysis can elucidate the complexity of human physiology and holds great potential to improve our understanding of a multitude of diseases, ultimately enhancing our strategies for their diagnosis, treatment and prevention. Consequently, it is essential to conduct MR analysis from a multi-organ perspective to comprehend the clinical implications of imaging traits amidst the complex interrelationships of organ systems.

In this paper, we carried out a systematic two-sample MR analysis to explore the causal relationships between multi-organ imaging and clinical endpoints. We consolidated GWAS summary statistics from 402 multi-organ imaging traits (with an average sample size $n \approx 35,000$) from the UK Biobank (UKB)[37] study along with 372 clinical outcomes (304 with more than 10,000 cases and 68 more with at least 5000 cases) sourced from the FinnGen project[27] (**Tables S1-S2**). Our focus was on three major brain MRI modalities: 1) 101 regional brain volumes[21] from structural MRI (sMRI); 2) 110 diffusion tensor imaging (DTI) parameters[23] from diffusion MRI (dMRI); and 3) 90 functional activity (amplitude[38]) and connectivity traits from functional MRI (fMRI)[25]. Furthermore, we incorporated 82 CMR traits extracted from short-axis, long-axis, and aortic cine cardiac MRI[39,40]. We also considered 11 abdominal MRI traits, measuring volume, fat, or iron content in seven organs and tissues[8], and eight DXA imaging traits that gauged the lengths of all long bones and the width of the hip and shoulder[3]. We applied 8 MR methods[41-49] to investigate bidirectional genetic causal links. The study design is presented in **Figure 1A,** while **Figure 1B** offers a high-level summary of our key findings. Additional details on these multi-organ imaging traits are provided in the **Methods** section.

RESULTS

Genetic causality between brain imaging and multi-organ diseases

We explored the causal relationship between brain imaging traits and multi-organ diseases. At a false discovery rate (FDR) 5% level ($P < 1.31 \times 10^{-4}$, adjusting for multiple testing for both directions), MR identified 33 significant genetic causal effects of 6 diseases (within 4 major categories) on 6 brain imaging traits. These categories included diseases of the nervous system, diseases of the circulatory system, diseases marked as

autoimmune origin, and diseases of the digestive system. Among these 33 significant

findings, 14 were associated with hypertension (9 with hypertension and 5 with essential

hypertension), 12 with Alzheimer's disease and dementia, 5 with autoimmune diseases,

1 with allergic asthma, and 1 with atrial fibrillation (**Table S3**).

Our results revealed that neurodegenerative conditions, including dementia and

Alzheimer's disease, could potentially impair functional activity across various networks.

Specifically, dementia and Alzheimer's disease were consistently found to compromise

the integrity of the default mode (β < -0.09, P < 2.19×10^{-5}, >6/8 MR methods significant),

dorsal-attention (β < -0.05, P < 2.24×10^{-5}, >5/8 MR methods significant), and

frontoparietal networks (β < -0.03, P < 4.53×10^{-5}, >5/8 MR methods significant) (**Fig. 2A**).

In addition to degenerative neurological diseases, we consistently observed causal effects

of hypertension on regional brain volume, fMRI traits, and DTI parameters. For example,

hypertension had negative causal effects on grey matter volume (β < -0.03, P < 1.30×10^{-10}

, 5/8 MR methods significant). Similarly, a potential negative effect of hypertension was

observed on the fractional anisotropy (FA) of the body of the corpus callosum tract (BCC,

β < -0.07, P < 1.12×10^{-6}, 6/8 MR methods significant) and the genu of the corpus callosum

(GCC, β < -0.01, P < 2.29×10^{-5}, 6/8 MR methods significant). Conversely, positive effects

were found on other DTI parameters, such as axial diffusivity (AD), mean diffusivity (MD)

and radial diffusivity (RD) of superior corona radiata (SCR), RD of BCC, as well as RD of

GCC (β > 0.01, P < 4.30×10^{-5}, 6/8 MR methods significant). It makes sense as lower MD

and higher FA values typically indicating better white matter health[50]. In addition, we

observed that hypertension was causally related to decreased functional connectivity of

the orbito-affective network (β > -0.05, P < 1.16×10^{-5}, 6/8 MR methods significant) (**Fig.**

2B). Autoimmune diseases were mostly found to affect DTI parameters, such as the AD

and MD of SCR (β < -0.04, P < 9.43×10^{-5}, >5/8 MR methods significant) (**Fig. 2C**).

Brain and other organ-related diseases may also be affected by structural or functional

changes in the brain. To investigate this, we used brain imaging traits as exposure

variables and clinical endpoints as the outcome variables. At an FDR 5% level (P < 1.31×10^{-4}

), we identified 12 significant relationships between 5 brain imaging traits and 3 types of

clinical endpoints (**Table S3**). Most of the significant imaging-disease pairs were related

to DTI parameters and the majority of the significant findings pertained to brain diseases (11/12). For example, we found that the RD of BCC and GCC was causally related to dementia (β < -0.31, P < 1.47×10^{-5}, >5/8 MR methods significant), and the FA of SCR was associated with an increased risk of Alzheimer's disease (β > 0.33, P < 6.24×10^{-5}, 7/8 MR methods significant) (**Fig. 2D**).

Causal genetic relationships between CMR traits and clinical outcomes

We assessed the potential causal effects from clinical endpoints to CMR measures of heart structure and function. We identified 137 significant results at an FDR 5% level (P < 6.95×10^{-4}), including 44 unique CMR traits of the ascending aorta (AAo), descending aorta (Dao), left atrium (LA), right ventricle (RV), and left ventricle (LV). These significant causal effects were identified in 20 unique clinical endpoints of 5 categories: diseases of the circulatory system (10/20), endocrine, nutritional and metabolic diseases (6/20), mental and behavioral disorders (2/20), diseases of eye and adnexa (1/20), as well as neoplasms (ICD2 & ICD-O-3, 1/20). Among the 137 significant findings, 117 were associated with heart-related diseases (114 diseases of the circulatory system and 3 cardiac arrhythmias), 15 with endocrine, nutritional and metabolic diseases, and 3 with mental and behavioral disorders (**Table S4**).

Causal effects of hypertension were widely observed on many LV traits, such as global and regional[51] myocardial-wall thickness (segments 1-16, β > 0.07, P < 6.44×10^{-5}, 7/8 MR methods significant) and radial strain traits (segments 7-9 and 12-15, β > 0.06, P < 8.14×10^{-5}, 7/8 MR methods significant). In addition to LV traits, hypertension also affected multiple other CMR traits. For example, it had negative causal impacts on Aao and Dao distensibility[52-54] (β < -0.10, P < 2.11×10^{-5}, 7/8 MR methods significant), as well as positive effects on AAo and Dao minimum/maximum areas (AAo_{max} and AAo_{min} areas, β > 0.10, P < 3.32×10^{-6}, 7/8 MR methods significant). The causal effects were also observed in several LA traits, such as negative effects on the left atrium ejection fraction (β < -0.07, P < 4.45×10^{-4}, 7/8 MR methods significant) as well as positive effects on left atrium minimum/maximum volumes (LA_{min} and LA_{max} volumes, β > 0.06, P < 4.72×10^{-4}, 6/8 MR methods significant). Similar to hypertension, we found that cardiovascular diseases and hypertensive diseases had causal effects on various LV traits, such as

regional myocardial-wall thickness, left ventricular myocardial mass, and regional radial strain. We further identified heart-related disorders that contributed to alterations in heart structure and function. Conditions such as atrial fibrillation and flutter, heart failure, and cardiac arrhythmias were primarily linked to LA traits, including negative effects on the left atrium ejection fraction (β < -0.07, P < 1.35×10^{-5}, 7/8 MR methods significant) and positive effects on LA$_{min}$ and LA$_{max}$ volumes (β > 0.07, P < 1.08×10^{-6}, 7/8 MR methods significant) (**Fig. 3A**).

We also observed causal effects of other diseases, such as endocrine, nutritional and metabolic disorders, on heart structure and function. For example, diabetes was observed to have negative effects on regional longitudinal strain (segment 2, |β|>0.03, P < 1.68×10^{-4}, 5/8 MR methods significant) and positive effects on right ventricular ejection fraction (β > 0.04, P < 1.73×10^{-4}, 5/8 MR methods significant). Additionally, type 2 diabetes led to a lower level of AAo$_{max}$ and AAo$_{min}$ areas (β < -0.04, P < 3.53×10^{-4}, 5/8 MR methods significant) and larger global and regional myocardial-wall thickness (segments 5-6 and 10-12, β > 0.03, P < 5.35×10^{-4}, 5/8 MR methods significant). Pure hypercholesterolemia and other metabolic disorders were causally linked to an enlarged left atrium stroke volume (β > 0.05, P < 3.31×10^{-4}, 5/8 MR methods significant). Moreover, hypothyroidism negatively affected regional radial strain (segment 12, β < -0.05, P < 3.31×10^{-4}, 5/8 MR methods significant) (**Fig. 3B**). It is also noteworthy that we found evidence suggestive of causality for brain disorders on heart phenotypes, such as a potential causal effect of dementia on right ventricular end-diastolic volume (β > 0.03, P < 2.42×10^{-4}, 5/8 MR methods significant), as well as mood disorders on regional myocardial-wall thickness (segments 8 and 12, β < -0.12, P < 4.81×10^{-4}, 5/8 MR methods significant) (**Fig. 3C**).

Structural and functional abnormalities within the heart may also increase the risk of multi-organ diseases, considering the role of the heart in pumping blood to all other organs[55]. We examined this direction by treating CMR traits as exposure variables and clinical endpoints as the outcomes. At an FDR 5% level (P < 6.95×10^{-4}), we identified 20 significant causal pairs, with most related to heart-related diseases and a small portion to diseases of the nervous system. Some of these examples correspond to well-known relationships. For example, larger left ventricular ejection fraction was consistently found

to reduce the risk of heart failure (β < -0.30, P < 2.38×10⁻⁴, 5/8 MR methods significant).

(**Fig. 3D**). We also found that CMR traits, such as regional myocardial-wall thickness

(segment 5), had causal effects on Alzheimer's disease (β < -0.60, P < 4.85×10⁻⁴, 5/8 MR

methods significant) (**Fig. 3E**).

Causal genetic links between abdominal imaging traits and clinical outcomes

We first examined the causal effects of multi-organ diseases on abdominal imaging traits,

including the volume or iron content of organs like the spleen, kidney, liver, lung, and

pancreas[8]. At an FDR 5% level (P < 1.40×10⁻³), we identified 62 significant causal

relationships between multi-organ diseases and abdominal imaging traits, after excluding

straightforward associations such as the link between obesity and both adipose tissue

volume and abdominal organ fat content. Notably, liver imaging traits constituted the

majority of these findings (34/62). Brain disorders were the most prevalent among the

significant relationships identified (23/62, mental and behavioral disorders (14) and

diseases of the nervous system (9)), followed by endocrine, nutritional and metabolic

diseases (18/62) (**Table S5**). These findings aligned with ongoing research on the complex

interplay between the brain and abdominal organs, such as the brain-gut connection[56-58],

brain-kidney connection[59,60], and brain-liver connection[61]. Specifically, Alzheimer's

disease and dementia were linked to a reduction in liver volume and percent of liver fat

(|β|>0.02, P < 1.28×10⁻⁴, 6/8 MR methods significant). Sleep apnea was observed to

positively influence the liver volume and the volume of abdominal subcutaneous adipose

tissue (β > 0.19, P < 9.61×10⁻⁴, 6/8 MR methods significant). Furthermore, alcohol use

disorder was associated with an increase in percent liver fat (β > 0.13, P < 2.09×10⁻⁵, 6/8

MR methods significant). In addition to the brain, we found that diabetes was causally

related to a higher percent of liver fat (β > 0.04, P < 2.75×10⁻⁵, 5/8 MR methods significant)

and increased pancreas fat (β > 0.5, P < 9.14×10⁻⁵, 5/8 MR methods significant).

Furthermore, we found some autoimmune, rheumatic and infectious diseases were

causally associated with lower levels of liver iron content (β < -0.04, P < 4.47×10⁻⁴, >6/8

MR methods significant) and larger spleen volume (β > 0.06, P < 4.47×10⁻⁴, 6/8 MR

methods significant) (**Figs. 4A-C**).

Next, we evaluated the opposite direction with abdominal imaging traits as exposure variables and multi-organ diseases as outcomes. At an FDR 5% level ($P < 1.40 \times 10^{-3}$), we identified 44 significant pairs, with heart-related diseases occupying 15 among them, followed by endocrine, nutritional metabolic disorders (10/44), disease of the respiratory system (4/44), blood and blood-forming (4/44), musculoskeletal and connective (4/44), and digestive system (4/44). The liver imaging traits were again the most frequent (35/44). For example, a higher percent of liver fat had causal effects on multiple heart-related diseases, such as angina pectoris, coronary angioplasty, coronary atherosclerosis, ischemic heart disease (wide definition), myocardial infarction (strict), as well as heart failure and coronary heart disease ($\beta > 0.13$, $P < 1.40 \times 10^{-3}$, 5/8 MR methods significant). Further, an enlarged spleen volume was linked to an increased risk of cardiovascular diseases, such as diseases of arteries, arterioles and capillaries ($\beta > 0.25$, $P < 1.12 \times 10^{-3}$, 5/8 MR methods significant). Beyond cardiovascular impacts, increased liver iron content significantly elevated the risk of anemias, particularly iron deficiency anemia ($\beta > 0.19$, $P < 9.80 \times 10^{-4}$, 5/8 MR methods significant). A causal relationship was observed between higher percent of liver fat and liver diseases ($\beta > 0.13$, $P < 1.40 \times 10^{-3}$, 8/8 MR methods significant), increased visceral adipose tissue volume and hernia of abdominal wall ($\beta > 0.72$, $P < 1.40 \times 10^{-3}$, 6/8 MR methods significant), as well as spleen volume and noninfective enteritis and colitis ($\beta > 0.13$, $P < 9.66 \times 10^{-4}$, 5/8 MR methods significant). Moreover, visceral adipose tissue volume led to an increased risk of asthma and chronic lower respiratory diseases ($\beta > 0.30$, $P < 1.10 \times 10^{-3}$, 5/8 MR methods significant) (**Fig. 4D**).

Causal genetic links between skeleton DXA traits and clinical outcomes

The skeletal system serves as the foundational support for the human body, and as such, skeletal abnormalities could potentially contribute to the risk of multi-organ diseases. We identified 8 causal pairs at an FDR 5% level ($P < 1.04 \times 10^{-4}$), spanning conditions related to both the circulatory system and the musculoskeletal and connective tissue. Notably, an extended torso length was linked to an increased risk of several cardiovascular conditions, such as coronary atherosclerosis and myocardial infarction ($|\beta| > 18.72$, $P < 1.40 \times 10^{-3}$, 5/8 MR methods significant). Furthermore, longer torso length was inked to several musculoskeletal and connective tissue disorders, such as internal derangement of the knee and meniscus derangement ($|\beta| > 21.20$, $P < 1.49 \times 10^{-5}$, 5/8 MR methods significant)

(**Fig. 5A**). We also uncovered potential causal effects of multiple organ diseases on DXA-derived skeleton traits. At an FDR 5% level ($P < 1.04 \times 10^{-4}$), we found 4 significant results that mainly on connective tissue disorders. For example, systemic connective tissue disorders and other systemic involvement of connective tissue were associated with lower average tibia height ($|\beta| > 0.0005$, $P < 3.61 \times 10^{-5}$, 5/8 MR methods significant) (**Fig. 5B** and **Table S6**).

Discussion

Observational studies have identified numerous links between imaging-derived phenotypes and clinical outcomes. However, these associations are often influenced by residual confounding, complicating the accurate inference of causal effect sizes[62]. MR allows for the inference of causal relationships between exposure and outcome variables. MR leverages the natural and random assortment of genetic variants during meiosis, making these variants ideal instrumental variables for discerning causal effects. In the present study, we evaluated the causal links between 402 multi-organ imaging traits and clinical outcomes through bidirectional MR. To circumvent the issue of sample overlap[63], which can bias the causal effect and has been overlooked in many current MR-based studies, we used a two-sample MR design and sourced our imaging and clinical data from different large-scale cohorts.

The interconnected nature of our organ systems suggested that diseases often affect more than one part of the human body[35,36,61,64]. The brain and heart are particularly critical, with the brain controlling a variety of functions, including reactions, emotions, vision, memory, and cognition[65,66], while the heart acts pumps oxygen and nutrient-rich blood to other organs. Dysfunctions in various organs can potentially have detrimental effects on the brain and heart, and vice versa. Besides connections to the brain and heart, we also uncovered many other causal relationships across different organs. In this causal discovery research, we implemented stringent criteria for selecting significant causal pairs (**Methods**), with the goal being to ensure that all reported findings are statistically robust and capable of offering potential biological insights. Consequently, the absence of certain causal pairs in our study does not imply a lack of causal relationships. Moreover, our findings should be interpreted carefully in the context of known biology. Whereas some

causal pairs are highly plausible and predictable based on current knowledge, many are

novel and unexpected. These should stimulate further research to discern potential

mechanistic pathways. A visualization of the interactions across different organ systems

can be found in **Figure 1B**. We will discuss our findings in more detail below.

Intra-brain causal connections.

As expected, alterations in brain structure and function were found to be closely linked

with brain disorders, with some of these relationships appearing to be bidirectional. We

consistently identified causal connections between brain imaging traits and a variety of

psychiatric disorders or neurological diseases, such as Alzheimer's disease, dementia,

mood disorder, and sleep apnea. For example, AD and dementia had an impact on fMRI

traits, which were primarily observed as indicators of AD and dementia. Prior studies have

consistently reported that resting fMRI connectivity patterns are disrupted in patients

with Alzheimer's disease[67,68], particularly in brain regions involved in memory and

cognitive function[69,70]. DTI abnormalities were found to be a precursor or an early sign of

brain pathology that could lead to brain-related disorders[71,72].

Brain-heart causal connections.

Despite the increasing number of association studies investigating the brain-heart

interaction[40,73], causal genetic links within these systems remain largely uncharted. In this

study, we identified causal connections from hypertension to DTI parameters in multiple

white matter tracts, including the SCR, BCC, and GCC. Additionally, hypertension had

causal effects on regional brain volumes and fMRI traits, such as the mean activity within

the orbito-affective network. These results could be attributed to the effects of

hypertension on cerebral small vessel health[74,75], leading to microvascular damage, which

can disrupt white matter integrity, alter brain function observable in fMRI, and contribute

to changes in brain structure, such as reduced regional volumes. Furthermore, elevated

blood pressure may cause ischemia and impair the blood-brain barrier, contributing to

neuroinflammation and neurodegeneration, reflected in these imaging traits[76-79]. Hence,

effective management of hypertension through lifestyle adjustments and medication

could help mitigate these adverse effects on the brain, which should be addressed in

future studies.

We observed that heart structural measures, such as regional myocardial-wall thickness, exhibited potential causal effects on Alzheimer's disease. Based on current knowledge, this connection does not seem to have clear underlying biologic plausibility, and should be interpreted cautiously until further knowledge is available regarding the role of cardiac abnormalities in the pathogenesis of Alzheimer's disease, which is at present incompletely understood[80,81]. Causal connections were also detected from the brain to the heart. We found that mental or degenerative neurological disorders can affect CMR traits, such as mood disorder affecting regional myocardial-wall thickness. The reason behind it may be related to the stress response, which can lead to increased levels of stress hormones such as cortisol and adrenaline[82,83]. These hormones can cause an increase in blood pressure and heart rate, leading to hypertrophy (thickening) of the myocardial wall over time as the heart works harder to pump blood[84,85]. Mood disorders may also cause lifestyle changes (such as changes in dietary and physical activity patterns) that have deleterious effects on blood pressure and vascular function. Inflammation may also be involved, since mood disorders have been associated with increased levels of systemic inflammation, which is a known risk factor for various forms of cardiovascular disease[86,87].

Bidirectional connections between the brain and abdominal organs.

Brain disorders were found to influence multiple abdominal organs. For example, we found that degenerative neurological diseases, such as Alzheimer's disease and dementia may exert potential causal effects on several abdominal imaging traits, such as liver fat and volume, visceral/abdominal subcutaneous adipose tissue volume, as well as lung volume. Patients with Alzheimer's disease and dementia often require multiple medications to manage symptoms, including antipsychotics, antidepressants, and medications aimed at slowing cognitive decline. Some of these medications can have hepatotoxic effects or interact with other drugs in ways that might impact liver function. Regular monitoring through liver function tests is important for patients on long-term medication regimens. Alzheimer's disease and dementia also might lead to systemic inflammation[88], which has been linked to abnormal intermediary metabolism, a key regulator of liver fat and function[89]. The connection between neurological disorders and

adipose tissue volume might be related to reduced physical activity[90] and corticosteroid medications[91]. The connection between Alzheimer's disease and lung phenotypes may be related to effects of neurological diseases on respiratory muscle weakness[92,93]. This weakness could subsequently influence lung volume and functionality. Similar to Alzheimer's disease and dementia, sleep apnea could also affect liver and adipose tissue. Whereas sleep apnea and liver/adipose tissue may have overlying common determinants, such as obesity, insulin resistance, decreased physical activity, and abnormal dietary patterns, sleep apnea may also impact various metabolic processes in its own right, which could contribute to further insulin resistance and fat accumulation in the liver. In addition to neurological diseases, our study revealed that alcohol use disorder can cause an increase in liver fat percentage. It is well documented that individuals suffering from alcohol use disorder are more prone to develop alcoholic fatty liver disease[94].

Conversely, brain imaging traits were causally affected by various diseases of other organs or systems. For example, we found that asthma influenced regional brain volumes. Interestingly, prior studies have demonstrated that individuals with asthma may have diminished cognitive function, including impaired memory and attention, as well as changes in brain activity patterns during cognitive tasks[95,96]. Anxiety, stress, and depression, which are often experienced by individuals with asthma, can also result in alterations to brain structure. Notably, autoimmune diseases (as defined by FinnGen[27]) impacted brain imaging traits, such as DTI parameters of the SCR. Multiple sclerosis, an autoimmune disease affecting the central nervous system, can cause damage to the myelin sheath that surrounds axons and can occur in various brain regions[97,98], including the internal capsule. This damage can disrupt neural connections passing through the anterior limb, leading to symptoms such as weakness, spasticity, and difficulty with balance and coordination. In rare autoimmune diseases, such as neuromyelitis optica[99] and autoimmune encephalitis, inflammation, and damage can occur in the brain. The resulting neurological symptoms can vary based on the severity and location of the damage[100,101]. Additionally, autoimmune diseases causing systemic inflammation, such as rheumatoid arthritis and lupus, could potentially affect the brain[102] and white matter tracts[103,104]. Chronic inflammation can lead to changes in the microstructure of white matter tracts, resulting in alterations in neural connectivity and function[105,106].

Intra-heart causal connections.

Bidirectional causal relationships were observed between cardiovascular diseases and CMR traits. Hypertension was found to causally influence several CMR traits across different heart chambers and aorta regions. Conversely, alterations in CMR traits were contribute causally to heart diseases. These findings are well-aligned with our current understanding of the effects of hypertension on the heart. For example, hypertension can cause changes in the heart's structure and function due to increased afterload, leading to left ventricular hypertrophy and changes in left atrial size,[107,108] which can in turn contribute to the development of various complications, including atrial fibrillation, heart failure, and stroke[109]. Additionally, changes in cardiac structure might influence blood pressure regulation, since from a hemodynamic standpoint, blood pressure is the direct result of interactions between the cardiac pump and its coupled vascular load[110].

Causal connections between the heart and abdominal organs.

Heart health was found to be causally linked with various multi-organ imaging traits or diseases. For example, liver fat was linked to multiple heart-related diseases, such as coronary atherosclerosis. This may be due to the key role of the liver in intermediary and lipoprotein metabolism, both of which are known contributors to the pathogenesis of atherosclerotic vascular disease. Additionally, heart failure was observed to cause an increase in spleen volume. The latter could be due to venous stasis and venous hypertension, which is a known consequence of heart failure. Indeed, increased venous pressure can lead to spleen enlargement, a condition known as splenomegaly[111]. Conversely, we found larger spleen volume to exhibit a causal effect on heart failure, a causal connection that is more difficult to interpret based on current knowledge, and which should stimulate further research. The pancreas also had causal effects on the cardiovascular system. For example, excess pancreas fat was associated with a higher risk of developing deep vein thrombosis of the lower extremities and pulmonary embolism. Pancreatic steatosis, a condition where fat accumulates in the pancreas, is linked with several metabolic abnormalities, including insulin resistance and inflammation, which can contribute to the development of cardiovascular diseases[112,113].

Causal connections between metabolic disorders and multiple organs.

Diabetes was found to have an adverse impact on heart structural variations in AAo, RV,

and LV. Multiple pathways may account for these causal associations, such as diabetic

cardiomyopathy[114], microvascular dysfunction[115,116], and metabolic disturbances[117].

Diabetes can also affect the fat accumulation in the liver and pancreas. The liver plays a

crucial role in managing glucose and fat metabolism. In the face of insulin resistance, the

liver can accumulate fat, leading to non-alcoholic fatty liver disease. Insulin resistance

prompts the liver to increase glucose production, contributing to high blood sugar levels,

while also interfering with the liver's ability to process fat, leading to fat accumulation.

Fat accumulation is not limited to the liver; it can also occur in the pancreas. The pancreas

is sensitive to the metabolic changes induced by insulin resistance and obesity. Excess fat

within the pancreas may affect its function, particularly the insulin-producing beta cells.

Studies suggest that fat accumulation in the pancreas can impair insulin secretion[118,119],

exacerbating the cycle of insulin resistance and beta-cell dysfunction seen in type 2

diabetes. Additionally, the excess fat (especially in the form of triglycerides) within the

pancreas can lead to beta-cell dysfunction[120]. This dysfunction further impairs the body's

ability to produce and regulate insulin effectively, worsening glucose control[121-123].

Skeleton DXA traits.

We found genetic causal connections between DXA-derived skeleton traits and multiple

organ diseases. MR typically reflects long-term effects rather than immediate impacts,

making it a highly suitable method to measure causal effects related to the skeletal

system. This is because skeletal traits are less prone to rapid modifications over short

periods. Skeletal traits were shown to be potentially causally affected by musculoskeletal

and connective disorders, which might have multiple pathways, such as altered bone

density[124], abnormal bone growth and formation, as well as inflammatory conditions.

Conversely, skeletal disorders could contribute to numerous organ diseases, with heart

conditions being the most prevalent in our analysis. However, the precise underlying

mechanisms of these potentially causal connection require further study.

Limitations and conclusions.

Our study has several limitations. First, our GWAS summary statistics were sourced from publicly available databases. Thus, we could not evaluate the impact of unobserved confounders, such as population stratification, on our results. Second, a common limitation that most existing MR methods share is that they require several model assumptions. This may result in model misspecifications and issues related to data heterogeneity when integrating data from different data resources[125]. We have systematically applied quality control measures and performed sensitivity analyses in our study. Future research implementing more advanced MR methods may relax some of these model assumptions[126,127]. Furthermore, MR studies are designed to examine the effects of lifetime exposure factors on outcomes, not interventions within a specified period. As a result, our findings may be interpreted differently than the rigorous results obtained from randomized controlled trials. Moreover, our findings have varying degrees of biologic plausibility based on current knowledge. They should therefore be interpreted accordingly, and reinterpreted as new mechanistic knowledge becomes available.

In conclusion, we used two-sample bidirectional MR analyses to comprehensively explore the multi-organ causal connections between 372 clinical outcomes and 402 image-derived phenotypes of various organ systems. Our results revealed robust genetic evidence supporting causal connections within and across multiple organs. These findings will be useful in understanding complex pathogenic mechanisms and will contribute to further mechanistic research and ultimately, to the early prediction and prevention of multi-organ diseases from a whole-body perspective.

METHODS

Methods are available in the ***Methods*** section.

Note: One supplementary table zip file are available.

ACKNOWLEDGEMENTS

Research reported in this publication was supported by the National Institute On Aging of the National Institutes of Health under Award Number RF1AG082938. The content is solely the responsibility of the authors and does not necessarily represent the official views of the National Institutes of Health. The study has also been partially supported by

funding from the Wharton Dean's Research Fund, Analytics at Wharton, and Purdue Statistics Department. Assistance for this project was also provided by the UNC Intellectual and Developmental Disabilities Research Center (NICHD; P50 HD103573). This research has been conducted using summary-level data from the UK Biobank study and the FinnGen research project. We would like to thank the individuals who represented themselves in the UK Biobank and FinnGen studies for their participation and the research teams for their efforts in collecting, processing, and disseminating these datasets. We would like to thank the research computing groups at the University of North Carolina at Chapel Hill, Purdue University, and the Wharton School of the University of Pennsylvania for providing computational resources and support that have contributed to these research results.

AUTHOR CONTRIBUTIONS

J.S. and B.Z. designed the study. J.S., C.C., B.L., Z. F., X.Y., Y.Y, X.W., and Y.L. analyzed the data. R.Z. and J.C. helped interpret findings. B.X., T.L., and H.Z. provided feedback on the results. J.S. and B.Z. wrote the manuscript with feedback from all authors.

METHODS

Multi-organ imaging traits.

The imaging data were sourced from the UK Biobank (UKB) study, which enrolled approximately 500,000 individuals aged between 40 and 69 from 2006 to 2010 (https://www.ukbiobank.ac.uk/). These multi-organ imaging data were collected from the ongoing UKB imaging study project (https://www.ukbiobank.ac.uk/explore-your-participation/contribute-further/imaging-study), which aims to collect brain, heart, and abdomen scans from 100,000 participants. Ethical approval for the UKB study was secured from the North West Multicentre Research Ethics Committee (approval number: 11/NW/0382).

Studies of brain and heart diseases usually rely on magnetic resonance imaging (MRI) scans, which are well-established clinical endophenotypes. Cardiovascular magnetic resonance imaging (CMR) is a set of MRI techniques that are designed to assess ventricular function, cardiovascular morphology, myocardial perfusion, and other cardiac functional and structural features[128,129]. They have been frequently used to reveal heart-related issues clinically. The CMR traits used in the paper were originally generated from the raw short-axis, long-axis, and aortic cine images using the state-of-the-art heart imaging segmentation and feature representation framework[39,130,131]. We divided the generated 82 CMR traits into 6 categories. The first two are aortic sections, namely ascending aorta (AAo) and descending aorta (DAo), which serve as the main 'pipe' in supplying blood to the entire body. The other four are the global measures of 4 cardiac chambers, including the left ventricle (LV), right ventricle (RV), left atrium (LA), and right atrium (RA), which altogether manage the heartbeat and blood flow. There are also some other traits, such as regional phenotypes of the left ventricle myocardial-wall thickness and strain (**Table S1**). The summary-level GWAS data of these 82 CMR traits were obtained from Zhao, et al. [40].

Brain MRI provides detailed information about brain structure and function[132], such as abnormal growth, healthy aging, white matter diseases, structural issues, and functional abnormalities. In this paper, the summary-level GWAS data were collected from recent multi-modal image genetic studies, including regional brain volumes from structural MRI[21,133] (sMRI), diffusion tensor imaging (DTI) parameters from diffusion MRI[23,134] (dMRI), and functional activity (that is, amplitude[38]) and functional connectivity phenotypes from resting functional MRI[25] (resting fMRI). In sMRI, we used ANTs[135] to generate regional brain volumes for cortical and subcortical regions and global brain volume measures. In dMRI, we used the ENIGMA-DTI pipelines[136,137] to generate tract-averaged parameters for fractional anisotropy, mean diffusivity, axial diffusivity, radial diffusivity, and mode of anisotropy in major white matter tracts and across the whole brain. For resting fMRI, we extracted phenotypes from brain parcellation-based analysis. We used the Glasser360 atlas[138], which divided the cerebral cortex into 360 regions in 12 functional networks[139]. We considered 90 network-level resting fMRI phenotypes that evaluated interactions and spontaneous neural activity at rest.

The 11 imaging traits from abdominal MRI were derived by Liu., et al[8] using deep learning methods in terms of volume, fat, and iron in several organs and tissues, such as the liver, spleen, kidney, lung, pancreas, and adipose tissue. Skeleton DXA traits, including all long bone lengths as well as hip and shoulder width, were derived by Kun, et al. [3] using deep learning methods on whole-body DXA images. All eight skeleton traits have been controlled for height.

FinnGen clinical endpoints.

We used 372 clinical endpoints (304 with more than 10,000 cases and 68 more with at least 5000 cases) collected by the FinnGen project, which were selected from the R9 release (https://www.finngen.fi/en/access_results). Our initial criterion for selecting diseases was to include those with more than 10,000 cases. For certain significant diseases, such as Alzheimer's disease and neoplasm, we further relaxed the case number cutoff to 5,000. The 372 clinical endpoints covered diseases from various categories, namely, mental and behavioral disorders, diseases of the nervous system, diseases of the eye and adnexa, diseases of the genitourinary system, diseases of the circulatory systems,

endocrine, nutritional and metabolic disorders, diseases marked as autoimmune origin, diseases of the respiratory system, diseases of the digestive system, diseases of blood and blood-forming, diseases of the musculoskeletal system and connective tissue, as well as some other endpoints. The definitions can be found at https://risteys.finregistry.fi/. The FinnGen data used in our study was obtained from separate cohorts than those supplying imaging traits, which were derived from the UKB study, thus ensuring there was no sample overlap. Detailed information of these 372 clinical variables can be found in **Table S2**.

Mendelian randomization analysis.

We examined the genetic causal relationships between the 402 imaging traits (101 brain regional volume traits, 110 brain DTI parameters, 90 network-level fMRI phenotypes, 82 CMR traits, 11 abdominal traits, and 8 skeleton DXA traits) and 372 clinical endpoints. Prior to conducting the Mendelian randomization (MR) analysis, we conducted standard preprocessing and quality control procedures. First, we selected genetic variants based on a significance threshold of 5×10^{-8} in the exposure GWAS data. To ensure the independence of the genetic variants used in MR, we implemented LD clumping with a window size of 10,000 and an r^2 threshold of 0.01, using the 1000 Genomes European ancestry data as a reference panel. We used the TwoSampleMR package (https://mrcieu.github.io/TwoSampleMR/) for harmonization, which enabled us to accurately align alleles between the selected variants in the exposure and the reported effect on the outcome.

We assessed the performance of 8 MR methods, which included Inverse variance weighted (fixed effect), Inverse variance weighted (multiplicative random effect), MR-Egger, Simple Median, Weighted Median, Weighted Mode, DIVW, GRAPPLE, and MR-RAPS[41,42,44-49,140], where MR Egger was used as the pleiotropy test and will not be included in the figures. To ensure the reliability of our results, we implemented several quality control procedures. We excluded causal estimates that relied on fewer than 6 genetic variants, as a larger number of genetic variants increases the statistical power of MR analysis[47,48]. We retained causal pairs that were significant in at least two out of the eight methods. We also screened for pleiotropy by using the MR-Egger intercept, the most used

method for testing the pleiotropy assumption. If a causal estimate failed the MR-Egger intercept test, we required that it have significant results in at least one of the robust MR methods, such as Weighted Median, Weighted Model, MR-RAPS, or GRAPPLE. Additionally, we require all the selected causal pairs to be significant in more than half of the methods.

Code availability

We made use of publicly available software and tools. Our analysis code will be made freely available at Zenodo.

Data availability

We used summary-level GWAS data in this study, which can be obtained from the FinnGen project (https://www.finngen.fi/en/access_results), BIG-KP (https://bigkp.org/), Heart-KP (https://heartkp.org/), and project-specific resources are detailed in Liu., et al [8] and Kun, et al. [3].

Figure legends

Fig. 1 Overview of study design and findings.

(**A**). An overview of our multi-organ imaging genetic study, investigating 372 clinical outcomes. We used diverse imaging traits including multi-modal brain, cardiac, abdominal, and skeletal DXA imaging to explore their relationships with the clinical endpoints. Our study encompasses a comprehensive range of brain imaging modalities, such as structural MRI, diffusion MRI, and resting-state fMRI. The cardiac imaging data comprise short-axis, long-axis, and aortic cine images. Volume, iron content, and percent fat were measured across 6 different abdominal organs and tissues, yielding in 11 image-derived abdominal phenotypes. Additionally, we included 8 skeleton imaging traits encompassing long bone lengths as well as hip and shoulder width. (**B**). A high-level summary of our bidirectional findings. The left panel displayed all the imaging traits that have been used in the study. The grey arrow demonstrates the main findings, such as the intra-brain, intra-heart, brain-heart, and brain-abdominal-organs causal connections. The right panel depicts the intricate web of causal interactions among various organs as

uncovered in our study. The width of an arrow corresponds to the volume of findings

associated with it.
