Abstract

Background: Pathogenic variants in cancer susceptibility genes can now be tested efficiently and economically with the wide availability of multi-gene panel testing. This has resulted in an unprecedented rate of identifying individuals carrying pathogenic variants. These carriers need to be counselled about their future cancer risk conferred by the specific gene mutation. An important cancer susceptibility gene is PALB2. Several studies reported risk estimates for breast cancer (BC) associated with pathogenic variants in PALB2. Because of the variety of modalities (age specific risk, odds ratio, relative risk, and standardized incidence ratio) and effect sizes of these risk estimates, a meta-analysis of all of these estimates of BC risk is necessary to provide accurate counselling of patients with pathogenic variants in PALB2. The challenge, though, in combining these estimates is the heterogeneity of studies in terms of study design and risk measure.

Methods: We utilized a recently proposed novel Bayesian random-effects meta-analysis method that can synthesize and combine information from such heterogeneous studies. We applied this method to combine estimates from twelve different studies on BC risk for carriers of pathogenic PALB2 mutations, out of which two report age-specific penetrance, one reports relative risk, and nine report odds ratios.

Results: The estimated overall (meta-analysis based) risk of BC is 12.80% by age 50 $(6.11\% - 22.59\%)$ and 48.47% by age 80 $(36.05\% - 61.74\%)$.

Conclusion: Pathogenic mutations in PALB2 makes women more susceptible to BC. Our risk estimates can help clinically manage patients carrying pathogenic variants in PALB2.

Keywords: Bayesian model, Odds ratio, Relative risk, Penetrance, Pathogenic variants

1 Introduction

Multi-gene panel testing has made it possible to test many cancer-susceptible genes afford-ably and efficiently (Plichta et al., 2016). This has enabled identification of an increasingly large number of patients carrying pathogenic variants in various cancer genes. This includes both well-studied high-risk genes such as BRCA1 and BRCA2 and relatively less-studied moderate-risk genes. PALB2 is one such moderate-risk gene whose mutations are considered to be a pre-disposing factor for breast cancer (BC) (Rahman et al., 2007; Wesoła and Jeleń, 2017; Poumpouri-dou and Kroupis, 2012) as well as other cancers (Jones et al., 2009). PALB2 mutations have been identified in approximately 0.6–2% of familial breast cancer (Hofstatter et al., 2011; Bogdanova et al., 2011; Dansonka-Mieszkowska et al., 2010).

Several studies have examined the impact of pathogenic variants in PALB2 on BC risk. Anto-niou et al. (2014)conducted a family-based study of 364 female PALB2 carriers from 154 families to estimate the age-specific BC risk (penetrance) for PALB2 carriers. They found that the risk of BC for these carriers compared to a general population was higher by eight to nine times among those younger than 40 years of age, six to eight times among those 40 to 60 years of age, and five times among those older than 60 years of age. Further, they estimated that the cumulative risk of BC for female PALB2 carriers was 14% (CI; 9 - 20) by 50 years of age and 35% (CI; 26 - 46) by 70 years of age. Another study (Casadei et al., 2011) reported that the risk of BC for women with PALB2 mutations is 2.3-fold (95% CI: 1.5 – 4.2) by age 55 and 3.4-fold (95% CI: 2.4 – 5.9) by age 85 compared to their female relatives without the mutation. Aloraifi et al. (2015) conducted a meta-analysis of several case-control studies with cases being women diagnosed with early onset BC (less than 50 years) and reported a pooled odds ratio of 21.4. There are several other studies reporting BC risk conferred by PALB2 mutations (Zheng et al., 2018; Rahman et al., 2007; Erkko et al., 2008; Kurian et al., 2017; Díaz-Zabala et al., 2022; Dorling et al., 2021). Overall, there is a substantial variability in reported estimates.

For clinical purposes, it is necessary to combine risk information available in this vast liter-

ature to determine the age-specific risk of BC, that is, penetrance of BC due to pathogenic variants in PALB2. This would greatly benefit individuals carrying such variants. However, there is a wide variability among the published studies in terms of study design (e.g., family-based, case-control) and type of reported result (e.g., age-specific penetrance, odds ratio (OR), relative risk (RR), standardized incidence ratio (SIR)). Standard random-effects meta-analysis methods cannot be applied due to the differences in the type of reported summary results across studies. Thus, a key challenge in this task is synthesising all available information on risk while accounting for heterogeneity in study design across studies.

We have recently developed a novel meta-analysis approach based on a Bayesian hierarchical random-effects model to obtain penetrance estimates (Ruberu et al., 2023). It integrates results from studies reporting different types of risk measures while accounting for uncertainties associated with such synthesis. We have also used it to estimate the age-specific penetrance of female BC among carriers of pathogenic variants in the ATM gene. In particular, the method can combine studies reporting age-specific penetrance, OR, RR, and SIR. To the best of our knowledge, this is the only method currently available in the literature to combine different types of risk measures while maintaining satisfactory statistical properties, in particular, low mean square error and coverage probabilities of interval estimates being close to the nominal (expected) confidence level. The only other method equipped to combine different types of risk measures is a fixed-effects approach (Marabelli et al., 2016), however, its interval estimates can suffer from under-coverage (Ruberu et al., 2023) and it does not address uncertainty quantification as completely as in Ruberu et al. (2023). In this article, we applied this novel Bayesian hierarchical random-effects model to conduct the first meta-analysis of penetrance of BC for pathogenic variants in the PALB2 gene.

2   Methods

2.1   Selection of Studies

First, we identified potential studies to include in the meta-analysis using a semi-automated natural language processing–based procedure for abstract screening (Deng et al., 2019). We also included additional studies using a Pubmed search of the following keywords in the title/abstract of the articles: "(((((mutation) OR (variant)) AND (PALB2)) AND (breast cancer)) AND (germline)" up to 10 May 2023. Our inclusion and exclusion criteria were the same as described in Ruberu et al. (2023). Specifically, we included (1) family-based segregation analyses or epidemiological studies reporting cancer risk information in terms of age-specific penetrance, RR, or SIR and (2) case-control studies comparing BC patients with healthy subjects and reporting either OR or sufficient data to estimate the OR and its 95% CI. We excluded case-control studies that ascertained subjects based on family history of BC but did not adjust for this ascertainment criterion in their estimation procedure as that can introduce bias in estimates (Kraft and Thomas, 2000). Moreover, we adjusted reported OR for a study to include only those mutations that are pathogenic as per ClinVar (Landrum et al., 2018), whenever that information was available. This resulted in inclusion of 12 studies in our meta-analysis, as summarized in Table 1.

2.2   Statistical Methods

To perform the meta-analysis, we employed a novel approach based on a Bayesian hierarchical random-effects model as described in Ruberu et al. (2023). Briefly, we combine estimates from S studies reporting point estimates as well as standard errors in one of four modalities: penetrance estimates/curve in an age range (e.g. $35-85$) or at few years such as $40, 50, \ldots, 80$, RR, SIR or OR. We assume that for all studies, the underlying cumulative risk $F_s(t|\kappa_s, \lambda_s)$ at age t is given by a Weibull distribution with study-specific parameters κ_s and λ_s. Each type of risk measure is

assumed to follow a normal distribution whose mean is a function of penetrance (i.e., Weibull parameters κ_s and λ_s) and variance reported by the study.

The prior distributions used in our model were chosen to produce a wide and realistic range of age-specific risks, so to be applicable to most gene-cancer applications. Specifically, we used the following hierarchical priors: $\kappa_s \sim \text{Gamma}(a, b)$, $\lambda_s \sim \text{Gamma}(c, d)$, where a and c are shape parameters, b and d are scale parameters, and $a \sim \text{U}(7.5, 27.5)$, $b \sim \text{U}(0.15, 0.25)$, $c \sim \text{U}(43, 63)$, and $d \sim \text{U}(1.32, 2.02)$. The posterior distributions were estimated by a Markov chain Monte Carlo algorithm, and used to estimate the consensus age-specific penetrance curve and its 95% credible interval. We carried out all analyses in the statistical software system R (R Core Team, 2020). The method is implemented in the R package BayesMetaPenetrance, available at `https://personal.utdallas.edu/~sxb125731/` and `https://github.com/LakshikaRuberu`.

3 Results

The penetrance estimate of BC for carriers of PALB2 pathogenic variants obtained by Bayesian meta-analysis is shown in Figure 1. The risk of BC is 12.80% by age 50 $(6.11\% - 22.59\%)$ and 48.47% by age 80 $(36.05\% - 61.74\%)$. For comparison, the figure also shows the age-specific risk estimates for non-carriers obtained using SEER (Surveillance, Epidemiology, and End Results) data. We also compared the meta-analysis curve with the estimates provided by each of the twelve individual studies in Figure 2, wherein for each study, we plot a Weibull penetrance curve that approximates the risk estimate provided by each study listed in Table 1. Note that the meta-analysis penetrance curve lies towards the center of the twelve curves. Notably, the contribution of each study to the final meta-analysis curve depends not only on the reported risk estimates but also on their standard errors (or confidence intervals) and sample sizes.

Among our 12 selected studies, two that reported OR included a subset of early-onset BC cases (Cybulski et al., 2015; Dorling et al., 2021) while one study included controls with ages

greater than 60 (Momozawa et al., 2018). We investigated how sensitive our results are to these studies by removing them one at a time. The resulting three penetrance curves are very close to the curve based on all 12 studies in Figure 3(a) showing that our final curve is robust to the exclusion of these studies. We note that OR for two studies, Ahearn et al. (2022) and Zheng et al. (2018) are quite high (17.25 and 20.384, respectively). These were the only two studies from Western Africa, specifically, Ghana and Nigeria. To investigate how sensitive the overall penetrances are to these two studies, we repeated the meta-analysis after removing these studies one at a time. The resulting penetrance curves are shown in Figure 3(b). We can see that they are close to the overall penetrance curve.

4   Discussion

Multi-gene panel testing has created an opportunity to identify people carrying mutations in a wide variety of cancer susceptibility genes (Plichta et al., 2016). PALB2 is one such gene which is now included in all BC gene-testing panels enabling identification of more people carrying pathogenic variants in the PALB2 gene (Tung et al., 2015). To counsel these carriers and help them mitigate their cancer risks, clinicians need estimates of age-specific risk (penetrance) associated with the pathogenic variants in PALB2. In this paper, we estimated penetrance for female BC by applying a novel Bayesian hierarchical random-effects meta-analysis method (Ruberu et al., 2023). To the best of our knowledge, this is the first meta-analysis to assess the penetrance of BC among female carriers of pathogenic mutations in PALB2.

Our results are consistent with the age-specific penetrance estimates for PALB2 mutations reported in the literature. Only two studies report age-specific penetrance estimates, namely Antoniou et al. (2014) and Erkko et al. (2008); both are included in our meta-analysis. As shown in Figure 2, the estimated meta-analytic penetrance curve lies between the two penetrance curves obtained from these studies.

We excluded studies that did not appropriately adjust for their ascertainment criteria based on family history in their analysis. Although we did include studies where participants were ascertained by age, our sensitivity analysis shows that the final estimates are robust to the inclusion of such studies. A limitation of our study is that neither of the two studies reporting penetrance provided results for ages less than 35. Moreover, none of the included OR/RR studies are age-specific. Therefore, the reported meta-analysis penetrance curve should be interpreted with caution for ages less than 35 due to the lack of direct empirical information.

In absence of meta-analysis based penetrance estimates of BC for PALB2 mutations, genetic counselling of PALB2 carriers with a family history of breast cancer is challenging (Wesoła and Jeleń, 2017). Counsellors would need to navigate the wide variability of estimates implied by the curves in Figure 2. The consensus estimate reported here is a principled compromise, whose credible band is far less wide than the variability of the individual risk estimates that were used to obtain it, owing to the strength of meta-analytic methodology. Thus it can help clinicians streamline the process of counselling carriers of pathogenic PALB2 mutations to mitigate their BC risk. Our final age-specific meta-analytic estimates has been incorporated into the PanelPRO R package — a Mendelian risk prediction model which estimates carrier probabilities and cancer risk for individuals with family history by integrating a large number of gene mutations and a wide range of potential cancer types based on available allele frequencies and penetrances (Lee et al., 2021; Ruberu et al., 2023).
