42 **Abstract**

43 **Background** | 5' untranslated regions (5'UTRs) are essential modulators of protein translation.
44 Predicting the impact of 5'UTR variants is challenging and typically not performed in routine
45 diagnostics. Here, we present a combined approach of a comprehensive prioritization strategy
46 and subsequent functional assays to evaluate 5'UTR variation in two large cohorts of patients
47 with inherited retinal diseases (IRDs).

48 **Methods** | We performed an isoform-level re-analysis of retinal RNA-seq data to identify the
49 protein-coding transcripts of 378 IRD genes with highest expression in retina. We evaluated
50 the coverage of these 5'UTRs by different whole exome sequencing (WES) capture kits. The
51 selected 5'UTRs were analyzed in whole genome sequencing (WGS) and WES data from IRD
52 sub-cohorts from the 100,000 Genomes Project (n = 2,417 WGS) and an in-house database (n
53 = 1,682 WES), respectively. Identified variants were annotated for 5'UTR-relevant features and
54 classified into 7 distinct categories based on their predicted functional consequence. We
55 developed a variant prioritization strategy by integrating population frequency, specific
56 criteria for each category, and family and phenotypic data. A selection of candidate variants
57 underwent functional validation using diverse experimental approaches.

58 **Results** | Isoform-level re-quantification of retinal gene expression revealed 76 IRD genes with
59 a non-canonical retina-enriched isoform, of which 20 display a fully distinct 5'UTR compared
60 to that of their canonical isoform. Depending on the probe-design 3-20% of IRD genes have
61 5'UTRs fully captured by WES. After analyzing these regions in both IRD cohorts we prioritized
62 11 (likely) pathogenic variants in 10 genes (*ARL3*, *MERTK*, *NDP*, *NMNAT1*, *NPHP4*, *PAX6*,
63 *PRPF31*, *PRPF4*, *RDH12*, *RD3*), of which 8 were novel. Functional analyses further supported
64 the pathogenicity of 2 variants. The *MERTK*:c.-125G>A variant, overlapping a transcriptional

65 start site, was shown to significantly reduce both luciferase mRNA levels and activity. The
66 *RDH12:c.-123C>T* variant was found *in cis* with the reported hypomorphic *RDH12:c.701G>A*
67 (p.Arg234His) variant in 11 patients. This 5'UTR variant, predicted to introduce an upstream
68 open reading frame, was shown to result in reduced RDH12 protein but unaltered mRNA
69 levels.

70 **Conclusions** | This study demonstrates the importance of 5'UTR variants implicated in IRDs
71 and provides a systematic approach for 5'UTR annotation and validation that is applicable to
72 other inherited diseases.

85

86 **Background**

87 Among the numerous non-coding regulatory regions found across the human genome, 5'
88 untranslated regions (5'UTRs) are major determinants of post-transcriptional control and
89 translation efficiency^{1,2}. These regions, with an average length of about 200 nucleotides in
90 humans, are located immediately upstream from protein-coding sequences and include the
91 Kozak consensus sequence around the AUG start codon³. 5'UTRs harbor numerous *cis*-
92 regulatory elements such as internal ribosomal entry sites (IRES) and upstream open reading
93 frames (uORFs), which can recruit scanning ribosomes and initiate translation⁴. In particular,
94 uORFs, defined by an upstream start codon in-frame with a stop codon preceding the end of
95 the primary open reading frame, can decrease downstream protein expression up to 80%⁵.
96 Furthermore, 5'UTRs can serve as platforms for the formation of secondary and tertiary mRNA
97 structures like stem-loops, hairpins, and RNA G-quadruplexes which further influence mRNA
98 translation^{6,7}. Given the critical importance of 5'UTRs as modulators of protein expression,
99 genetic variation within these regions can contribute to disease pathogenesis, as shown by
100 several examples in a wide range of inherited diseases⁸⁻¹¹.

101 With the expanding implementation of massively parallel sequencing technologies in clinical
102 practice, the rare disease field has witnessed a true paradigm shift enabling improved
103 molecular diagnosis for many affected individuals¹²⁻¹⁵. Despite these advancements, and
104 although this varies greatly across individuals with diverse clinical indications, a significant
105 fraction of cases with suspected Mendelian disorders remains unsolved^{12,13,16-18}.

106 To date, 5'UTR variants are often not evaluated because of the multiple challenges they entail.
107 Firstly, detection relies on inclusion of these non-coding regions in targeted resequencing
108 panels or whole genome sequencing, which has been limited to date¹⁹. Secondly,
109 interpretation of the effect is more difficult due to different mechanisms⁸ and our relative lack

110 of understanding of the functional consequences of 5'UTR variants. Finally, functional
111 evidence is necessary to support their pathogenicity and hence confirm the molecular
112 diagnosis. Recently, to close the annotation and interpretation gap, several *in silico* tools^{20–26}
113 and guidelines²⁷ have been developed, although their specific applicability to the accurate and
114 comprehensive interpretation of the diverse pathogenic mechanism of 5'UTR variants is yet
115 to be fully established.

116 A clear instance of both the effectiveness and remaining challenges of clinical large-scale
117 genome analyses can be found in inherited retinal diseases (IRDs)^{28–31}. IRDs comprise a
118 genetically and phenotypically diverse constellation of visually debilitating conditions
119 affecting over 2 million people globally^{32,33}. With over 290 known disease genes³⁴, diverse
120 modes of inheritance²⁹, intersecting phenotypes^{35,36}, and available automated approaches to
121 variant interpretation, establishing a genetic diagnosis in IRD patients can be challenging. Even
122 after the use of unbiased approaches such as whole exome (WES) and whole genome
123 sequencing (WGS), up to 50% of cases remain unsolved^{15,28,37–39}, and hence without the
124 possibility of potential clinical intervention including gene therapy-based treatments^{40,41}.

125 Recent studies have revealed an important contribution of non-coding variation to IRDs,
126 particularly with the identification of deep-intronic mis-splicing variants^{39,42,51,43–50}. Moreover,
127 there is a growing body of evidence supporting the emerging role of genetic variation affecting
128 *cis*-regulatory regions in the molecular pathogenesis of IRDs^{45,48,52–56}. However, thus far only
129 a few 5'UTR variants have been reported to be implicated in ocular diseases, including
130 IRDs^{48,53,54,57–59}, but no large-scale studies have been performed yet.

131 In this work, we conducted a systematic evaluation of 5'UTR variation in IRD genes using WGS
132 and WES data derived from two IRD cohorts comprising 2,417 participants of the 100,000
133 Genomes Project¹² and 1,682 local cases, respectively. Firstly, we obtained a comprehensive

134 selection of 5'UTRs of the most abundant canonical as well as non-canonical protein-coding
135 IRD gene isoforms by performing transcript-level re-quantification of retinal expression data.
136 We then screened these regions for variants in both IRD cohorts and developed a prioritization
137 strategy to identify candidate pathogenic 5'UTR variants. This allowed us to identify 11
138 potentially causative 5'UTR variants, 10 of which were found in unsolved cases. Functional
139 validation of the predicted pathogenetic mechanism was performed for 4 of these, further
140 supporting the potential implication in disease for 2 variants. Overall, we show that 5'UTRs
141 represent understudied targets of non-coding variation that can provide novel molecular
142 diagnoses in IRDs and demonstrate the importance of reassessing these regions in existing
143 exome and genome sequencing data.

144 **Methods**

145 **Re-analysis of retinal RNA-seq data and selection of retina-enriched isoforms of IRD genes**

146 We retrieved paired-end FASTQ files (GSE115828) derived from human postmortem retina
147 samples characterized by Ratnapriya *et al.*, (2019)⁶⁰. Only samples derived from donor retinas
148 showing no features of age-related macular degeneration were evaluated (n=102). Transcripts
149 were quantified through pseudoalignment by *Kallisto*⁶¹ (v.0.46.1) using default parameters.
150 Abundance estimates in transcripts per million (TPM) for all annotated transcripts (*Ensembl*
151 human release 107) were retrieved. A custom R (v.4.0.2) script was used for annotating each
152 transcript with its corresponding gene and biotype and flagging them as canonical and/or
153 belonging to the Matched Annotation from NCBI and EMBL-EBI (MANE) and MANE Plus
154 Clinical set (version 1.0)⁶². For each group of isoforms belonging to each gene, we computed
155 the average of abundance estimates across all samples and the isoform exhibiting the highest
156 average among its corresponding group was deemed retina-enriched. This dataset was further

157 filtered by retaining only protein-coding isoforms derived from selected genes, namely IRD
158 genes listed in either the *Retinal disorders panel* (v2.195) from Genomics England PanelApp⁶³
159 or RetNet (<https://sph.uth.edu/retnet/>) (**Table S1**). Additionally, we integrated cap analysis
160 gene expression sequencing (CAGE-seq) data derived from fetal and adult retina (FANTOM5⁶⁴
161 Robust Peak Set using an expression RLE normalized threshold >1) to evaluate the confidence
162 of the annotated transcription start sites (TSS) of the selected transcripts in retina.
163 To aid tiering of variants, the Genomics England PanelApp⁶³ gene color-coded rating system
164 was used: genes with diagnostic-grade rating, borderline evidence and research candidates
165 were flagged with green, amber, and red, respectively. To further assess the retina-
166 enrichment of specific isoforms, their loci were inspected using an integration of multiple
167 publicly available multi-omics datasets derived from human retina (**Table S2**).

168 **Comparison of 5'UTRs of canonical and non-canonical isoforms and selection of 5'UTR** 169 **variant search space**

170 The exact genomic coordinates of the start and end positions of the 5'UTRs of all genes were
171 downloaded from *Ensembl biomart* (Human Ensembl Genes 107, GRCh38.p13) and filtered to
172 only include the transcripts defined above. We first assessed the number of exons composing
173 these 5'UTRs to identify which IRD genes have spliced 5'UTRs. For each IRD gene for which a
174 retina-enriched non-canonical isoform was identified, we compared the canonical and non-
175 canonical 5'UTRs and computed their respective overlap. The calculated overlaps were then
176 used to classify these genes into three different categories, namely genes with transcripts
177 displaying: (i) fully distinct 5'UTRs, (ii) partly overlapping 5'UTRs, and (iii) fully overlapping
178 5'UTRs.

179 For each 5'UTR exon of all selected transcripts, we defined a near-splice region by including
180 25-bp intronic sequence up- and downstream of its respective splice donor and acceptor sites

181 (excluding promoter and coding sequences). The resulting coordinates were annotated with
182 their corresponding transcript identifier and gene name and stored into a sorted BED file
183 (herein after referred to as *5'UTR analysis file*) for downstream variant assessment.

184 **Evaluation of 5'UTR capture by whole-exome sequencing**

185 We assessed the performance of exome captures of the selected 5'UTRs based on the designs
186 provided by the kits which were mostly used for the generation of our in-house WES data,
187 namely the SureSelect Human All Exon V6 and SureSelect Human All Exon V7 (Agilent
188 Technologies), as well as a selection of the most recent versions of commonly used kits from
189 4 different providers: SureSelectXT Human All Exon V8 (Agilent Technologies), KAPA
190 HyperExome V2 (Roche), Twist Exome 2.0 (Twist), Illumina Exome Panel v1.2 (Illumina). BED
191 files containing the genomic coordinates of the capture regions were downloaded from the
192 corresponding design catalogs and intersected with the coordinates of the 5'UTRs of interest
193 using *bedtools intersect* (v2.26.0)⁶⁵ with default parameters. For uniformity, only the capture
194 regions were used to compare between the different designs. Additionally, for the SureSelect
195 Human All Exon V6 and SureSelect Human All Exon V7 kits (Agilent Technologies) both the
196 strict union of all regions covered by baits and a version padded by ± 50 bp extending into
197 intronic regions were considered for the intersections. A custom Python (v.3.6.8) script was
198 then used to compute for each IRD gene the length proportion (%) of its 5'UTR captured by
199 these kits.

200 **Search of 5'UTR variants in IRD genes submitted to ClinVar**

201 The ClinVar database (ClinVar) was downloaded in a tab-delimited format⁶⁶ directly from the
202 FTP site (<https://ftp.ncbi.nlm.nih.gov/pub/clinvar/>; version from 2023-03-18) and pre-filtered
203 to keep only entries from the GRCh38.p13 build. The resulting file was further filtered to

204 retrieve variants located within the regions defined in the *5'UTR analysis file*. Large copy
205 number gain/loss variants extending into coding regions as well as variants with a protein-
206 altering or synonymous annotation for the canonical transcript were removed from this
207 analysis.

208 **Cohort selection**

209 To assess the contribution of 5'UTR genomic variation to IRDs, individuals from two different
210 cohorts were selected for this study: (i) 2,397 participants (2,100 probands) from a sub-cohort
211 of the Rare Disease arm of the 100,000 Genomes Project (Genomics England –GE– cohort)
212 affected by posterior segment abnormalities (**Table S3**); (ii) an IRD sub-cohort of 1,682 cases
213 (1,030 probands) with a WES analysis performed at the Center for Medical Genetics Ghent
214 (CMGG cohort). In both cases, sequencing data aligned to GRCh38 build were included.

215 The 100,000 Genomes Project Protocol has ethical approval from the HRA Committee East of
216 England – Cambridge South (REC Ref 14/EE/1112). This study was registered with Genomics
217 England within the *Hearing and sight* domain under Research Registry Projects 465. This study
218 was approved by the ethics committee for Ghent University Hospital (B6702021000312) and
219 performed in accordance with the tenets of the Helsinki Declaration and subsequent reviews.

220 **Sequencing and variant analysis**

221 We interrogated WGS and WES data from the two cohorts described above to detect germline
222 single-nucleotide variants (SNVs) and small insertions and deletions (indels) overlapping the
223 regions defined in the *5'UTR analysis file*. The sequencing and bioinformatic pipelines used for
224 processing genome data derived from the participants of the GE cohort have been described
225 previously¹².

226 Samples from the CMGG cohort were tested using WES with the SureSelect Human All Exon
227 V6, SureSelect Human All Exon V7 (Agilent Technologies) or HyperExome (Roche) enrichment
228 kits and sequenced on HiSeq 3000 or NovaSeq 6000 instruments (paired-end 150 cycles)
229 (Illumina). Reads were aligned to the human reference genome (GRCh38 build) with *BWA*
230 (v0.7.15)⁶⁷ and *GATK HaplotypeCaller* (v3.82)⁶⁸ was used for calling SNVs and indels. Resulting
231 variant call format (VCF) files from both cohorts were subsequently parsed based on the
232 regions of interest using *BCFtools* (v1.9)⁶⁹. Only variants satisfying the filter criteria for
233 sequencing depth (DP>10) and genotype quality (GQ>15) were retrieved.

234 **Variant annotation and prioritization**

235 From each cohort, a file containing unique variants was created and formatted so that it could
236 be annotated with the *Ensembl Variant Effect Predictor*⁷⁰ (VEP, release 107). Apart from gene
237 and transcript information, each variant was annotated with frequency data retrieved from
238 gnomAD⁷¹ (genomes, v3.1.2) allele frequencies, splicing (dbSNV⁷², SpliceAI²³,
239 MaxEntScan⁷³), pathogenicity predictions (EVE⁷⁴, CADD⁷⁵), and regulatory data⁷⁶. The recently
240 developed *UTRannotator*²⁰ tool was used to annotate variants that create or disrupt uORFs.
241 The classical⁷⁷ and retinal⁷⁸ Kozak consensus sequences were considered altered when
242 variants were identified within the position range -1 to -10 relative to the main AUG (canonical
243 start codon). In addition, nucleotide frequency plots corresponding to the Kozak sequences of
244 the retina-enriched and not retina-enriched transcripts evaluated in this study were generated
245 using were generated with *WebLogo*⁷⁹ (v.3.7.12). Annotation data tables containing predicted
246 changes in translational efficiency⁸⁰ and secondary structure minimum free energy affecting
247 double-stranded RNA or G4 quadruplex structures⁸¹ were downloaded (*5utr* ['suter']:
248 <https://github.com/leklab/5utr>) and queried for the variant positions using *tabix*⁸² (v.1.7-2);
249 further evaluation of changes in mRNA secondary structure was performed using the *Ufold*⁸³

250 (v.1.2), *REDfold*⁸⁴ (v1.14.alpha), and *MXfold2*⁸⁵ (v0.1.2) tools. To assess whether variants were
251 located within TSS relevant to retinal gene expression, we made use of the CAGE-seq data
252 described above. Translation initiation-related feature data from the Human Internal
253 Ribosome Entry Sites (IRES) Atlas⁸⁶ was also queried to annotate variants found within these
254 regions involved in cap-independent translation initiation.

255 Annotated 5'UTR variants were classified into the following 7 categories: (i) uAUG gained, (ii)
256 change in existing uORF, (iii) alteration of classical or retinal primary Kozak context, (iv)
257 splicing, (v) change in translational efficiency (TE), (vi) change in secondary structure minimum
258 free energy, and (vii) overlapping a retinal transcription start site and/or an IRES. Variants
259 were first selected when their minor allele frequency was lower than 2% in all populations.
260 The resulting variants were further filtered using specific criteria for each category: (i) uAUG
261 created in a strong or moderate Kozak context, (ii) natural uAUG loss, (iii) variant located in
262 positions -3, -4, -5, -6, or -9, (iv) any SpliceAI Delta Score (DS_AG, DS_AL, DS_DG, DS_DL) higher
263 than 0.2, (v) $|\log_2FC| \geq 0.5$, (vi) $|FC| \geq 1.5$, (vii) variant located within a TSS or IRES. Variants for
264 which the inheritance pattern and phenotype of the patient were compatible with the gene
265 in which the 5'UTR variant was identified were selected as candidates. This prioritization
266 procedure is depicted in **Figure 1**. For comparing the proportion of variants for each category
267 between cohorts, the statistical analysis was performed in R using the χ^2 -test. Finally, for each
268 candidate variant identified in unsolved cases, an additional screening was performed to
269 discard (likely) pathogenic variants, both SNVs and structural variants (SVs), in other IRD genes
270 that could provide an alternative molecular diagnosis. For the cases from the GE cohort in
271 which the identified 5'UTR variant remained as candidate, we requested to have a clinical
272 collaboration with Genomics England.

273 **Cell culture**

274 ARPE-19 (ATCC, CRL-2302™) and HEK-293T cells (ATCC CRL-3216™) cells were grown in either
275 Dulbecco's minimal essential medium (DMEM) with phenol red (Thermo Scientific Life
276 Technologies) or DMEM:F12 (Gibco) medium supplemented with 10% fetal bovine serum
277 (Gibco), 1% penicillin-streptomycin (Gibco), 1% non-essential amino acid solution (Gibco), and
278 0.1% amphotericin B (Gibco), respectively. Cells were cultured at 37°C and 5% CO₂ and tested
279 for mycoplasma contamination prior to use.

280 To perform functional studies of the identified 5'UTR *ARL3* variant, lymphocytes from affected
281 carriers (n=2) were isolated from EDTA blood using Lymphoprep (STEMCELL technologies). For
282 each sample two cultures were started in RPMI medium with 10% fetal bovine serum and
283 substituted with interleukin-2 and phytohaemagglutinin. One of both cultures was treated for
284 four hours with puromycin (200 µg/mL) prior to RNA extraction to suppress nonsense-
285 mediated decay.

286 **Cloning and mutagenesis**

287 In order to evaluate the functional effect of 3 selected 5'UTRs variants (*RDH12:c.-123C>T*,
288 *MERTK:c.-125G>A*, *PAX6:c.-44C>T*), we cloned the wild-type 5'UTR of interest (IDT gBlock) into
289 a psiCHECK™-2 dual luciferase vector (Promega) using the Cold Fusion cloning kit (Sanbio BV).
290 The recombinant vectors were then amplified in One Shot TOP10 Chemically Competent *E.*
291 *coli* cells (Invitrogen) and purified using the NucleoBond Xtra Midi kit (Filter Service S.A). For
292 the generation of the overexpression construct to further assess the *RDH12:c.-123C>T* variant,
293 we designed a gBlocks™ fragment comprising the wild-type 5'UTR and coding sequence (CDS)
294 of *RDH12*; both sequences were modified to include downstream Myc and FLAG in-frame tags
295 to evaluate the translation of the uORF introduced by the *RDH12:c.-123C>T* variant and *RDH12*
296 protein levels, respectively. These fragments were then cloned into a pcDNA™3.1(+)
297 (Invitrogen) vector by restriction-ligation cloning and the recombinant vectors were amplified

298 and purified as described above. For all constructs, 5'UTRs variants were introduced using the
299 Q5 Site-Directed Mutagenesis Kit (NEB) using variant-specific primers designed with the
300 *NEBaseChanger* tool. The sequence of each insert was confirmed by Sanger sequencing using
301 the BigDye Terminator v3.1 kit (Life Technologies) and/or long-read whole plasmid sequencing
302 (Plasmidsaurus). A schematic overview of these constructs is shown in **Figure S1**. All primer
303 sequences can be found in **Table S4**.

304 **Dual luciferase assays**

305 ARPE-19 cells were seeded in a 24-well plate (Greiner Bio-One BVBA) at a density of 50,000
306 cells/well in 1mL of medium without antibiotics to reach 70-90% confluence at transfection
307 (18-24h after plating). Cells were transfected at a 3:1 reagent to plasmid DNA ratio using the
308 TransIT-X2[®] Dynamic Delivery System (Mirus Bio) according to the manufacturer's
309 instructions. After 24 h, cells were lysed, and luciferase activity was detected using the Dual-
310 Glo[®] Luciferase Assay System (Promega) in a Glomax 96-Microplate Luminometer (Promega).
311 Each transfection was performed in triplicate and each experiment was repeated at least three
312 times to ensure reproducibility. For each well, the ratio of *Renilla* luciferase activity was
313 normalized to *Firefly* luciferase activity. A custom R script was used to evaluate the effect of
314 each variant on luciferase activity through a linear mixed effects model (implemented in the
315 *lme4* package⁸⁷) having set the luciferase vector as fixed effect and the biological replicate as
316 random effect.

317 **RNA isolation and quantitative polymerase chain reaction (qPCR)**

318 Total RNA was extracted using either the RNeasy Mini kit[®] (Qiagen) (ARPE-19 and HEK-293T
319 cells) or the Maxwell RSC simply RNA kit (Promega) (cultured lymphocytes) according to the
320 manufacturer's instructions. Isolated RNA underwent DNase treatment (ArcticZymes, Tromsø,

321 Norway) prior to cDNA synthesis with the iScript cDNA Synthesis Kit (Bio-Rad Laboratories).
322 For each cDNA sample, qPCR assays were prepared using SsoAdvanced Universal SYBR Green
323 Supermix (Bio-Rad Laboratories) and run on LightCycler 480 System (Roche). Data were
324 analyzed with *qbase+*⁸⁸ (CellCarta, v.3.4) and normalized either to a set of housekeeping
325 genes (*YWHAZ*, *HPRT1*, *HMBS*, *SDHA*) or *Firefly* luciferase for normalization of *Renilla*
326 luciferase mRNA levels. All primer sequences can be found in **Table S4**. Statistical analyses
327 were performed in R using the Wilcoxon rank sum test.

328 **Overexpression and immunoblotting**

329 To perform immunoblotting of RDH12 and the predicted peptide encoded by the uORF
330 introduced by the *RDH12:c.-123C>T* variant, ARPE-19 cells were seeded in 12-well plates
331 (Greiner Bio-One BVBA) at a density of 100,000 cells/well, allowed to settle overnight, and
332 then transfected with the wild-type and mutant *RDH12* overexpression vectors using the
333 TransIT-X2[®] Dynamic Delivery System (Mirus Bio) according to the manufacturer's
334 instructions. The pcDNA[™]3.1⁽⁺⁾ (Invitrogen) backbone vector was transfected as negative
335 control. Four hours prior to RNA and protein isolation, cells were treated with 10 μ M MG-132
336 proteasome inhibitor (Merck Life Science). For total protein extraction, cells were lysed with
337 RIPA Buffer (Sigma-Aldrich) including protease inhibitory cocktail (Roche Diagnostics),
338 phosphatase inhibitory cocktail 2, and phosphatase inhibitory cocktail 3 (Sigma-Aldrich).
339 Protein concentrations were measured using the Pierce[™] BCA Protein Assay kit (Fisher
340 Scientific). After centrifugation and reduction with 1M DTT (Sigma-Aldrich), protein lysates
341 were subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis using either
342 NuPAGE[™] 4–12% Bis-Tris (RDH12 blot) or Novex[™] 16% Tricine (uORF blot) Protein Gels (Fisher
343 Scientific) with a ladder (Precision Plus Protein All Blue Standards, Bio-Rad Laboratories).
344 Proteins were then transferred to a nitrocellulose membrane using the iBlot 2 Dry Blotting

345 System (Thermo Fisher Scientific). Membranes were blocked for 2 hours at room temperature
346 in 2% ECL™ Blocking Agent (Cytiva Amersham) and incubated at 4°C overnight with anti-FLAG
347 (1:1000, F1804, Merck Life Science) or anti-Myc (1:1000, ab9106, Abcam) primary antibodies.
348 Membranes were subsequently incubated for 2 hours at room temperature with the
349 appropriate horseradish-peroxidase-conjugated secondary antibody (1:2500, 7076S or 7074S,
350 Cell Signaling Technologies) and revealed with the SuperSignal™ West Dura Extended Duration
351 Substrate (Fisher Scientific). Membranes were scanned with an Amersham Imager 680 system
352 (GE Healthcare Life Sciences). Protein quantification was performed by firstly stripping the
353 membranes with Restore™ PLUS Western Blot Stripping Buffer (Thermo Scientific), incubating
354 them for 1 hour at room temperature with a primary antibody against β -tubulin (1:2500,
355 ab6046, Abcam) and for 2 hours with a horseradish-peroxidase-conjugated secondary
356 antibody (1:2500, 7074S, Cell Signaling Technologies). RDH12 (FLAG) signal intensity
357 quantification was achieved using *ImageJ* (NIH, v.1.50i) and normalized to the amount of β -
358 tubulin.

359 To further assess the translation of the peptide encoded by the uORF introduced by the
360 *RDH12:c.-123C>T* variant, transfected HEK-293T cells were lysed as previously described, and
361 protein lysates incubated at 4°C overnight with Dynabeads Protein A (Thermo Fisher
362 Scientific), to which the anti-Myc primary antibody (1:1000, ab9106, Abcam) was bound.
363 Bound proteins were subsequently eluted and subjected to anti-Myc Western Blot analysis as
364 described above. Statistical analyses were performed in R using the Student's t-test.

365 **Screening of *RDH12: c.-123C>T* variant**

366 The *RDH12:c.-123C>T* 5'UTR variant was shared with members of the European Retinal
367 Disease Consortium (ERDC: <https://www.erd.c.info/>) to evaluate its pathogenicity and identify

368 additional carriers of the *RDH12*:c.701G>A (p.Arg234His) missense variant to confirm its *cis*-
369 configuration. Primer sequences for PCR and Sanger sequencing are listed in **Table S4**.

370 **Results**

371 **Isoform-level re-quantification of retinal gene expression reveals differential 5'UTRs of IRD** 372 **genes**

373 To obtain a relevant selection of 5'UTRs for downstream variant screening, we performed a
374 transcript-level re-analysis of RNA-seq data to identify protein-coding non-canonical isoforms
375 with relevant retinal expression i.e., higher than its respective canonical isoform, to be
376 retained in addition to the canonical isoforms. A total of 454 canonical and non-canonical
377 transcripts belonging to 378 IRD genes were thus selected (with maximum of 2 isoforms per
378 gene) (**Table S5**), from which their 5'UTRs were retrieved, resulting in 638 genomic regions
379 (**Table S6**). Considering these 454 transcripts, the 5'UTRs of approximately 62% of IRD genes
380 (233/378) are only part of the first coding exon while 33% of IRD genes (126/378) have
381 exclusively transcripts with spliced 5'UTRs, i.e., their 5'UTR comprise additional full non-coding
382 exons. A minor fraction (19/378) of genes has isoforms with both spliced and non-spliced
383 5'UTRs (**Figure 2A; Table S7**). Of the 76 IRD genes for which a retina-enriched non-canonical
384 isoform was identified, 20 display a fully distinct 5'UTR compared to the one of their
385 corresponding canonical isoforms (**Figure 2B; Table S8**). For six of these, the non-canonical
386 TSS is further supported by CAGE-seq data derived from both adult and fetal retina (**Table S5;**
387 **Figure S2**). Two remarkable examples are *CRB1* and *RIMS2*, for which the non-canonical
388 isoforms (ENST00000681519.1: 48.38±14.97 TPM; ENST00000436393.6: 41.58±12.35 TPM)
389 were found to be more abundant in retina compared to their respective canonical isoforms
390 (ENST00000367400.8: 2.54±3.88 TPM; ENST00000696799.1: 12.19±3.85 TPM). These findings

391 were also supported by the integration of multiple multi-omics datasets derived from human
392 retina (**Figure S3; Table S2**).

393 **A substantial fraction of 5'UTRs can be captured by whole-exome sequencing**

394 In view of the large volume of existing WES data, we evaluated the performance of six recent
395 and commonly used commercial exome capture designs from four different providers on the
396 selected 5'UTRs of IRD genes. The kits considered in this analysis were found to display a
397 variable performance with an average coverage of the selected 5'UTRs ranging from 7% (Twist
398 Exome 2.0) to 39% (Illumina Exome Panel v1.2) (**Figure 3A; Table S9**). Besides, the fraction of
399 IRD genes with 5'UTRs fully captured ranged from 3% (10/378) to 20% (73/378). Regarding
400 the kits that were mostly used in-house (SureSelect Human All Exon V6 and SureSelect Human
401 All Exon V7), although a slightly higher 5'UTR capture was observed for the kit with a higher
402 amount of probes (SureSelect Human All Exon V6) (**Figure S4; Table S10**), we found that
403 approximately 15% of IRD genes (57/378) have the selected 5'UTRs fully captured. This
404 fraction increased up to 39% (148/378) (**Figure 3B; Table S10**) if a padded bait design,
405 including all regions that can be confidently genotyped, was considered.

406 **A retrospective analysis of 5'UTR variants reported in IRD genes reveals a majority classified** 407 **as Variants of Uncertain Significance (VUS)**

408 A total of 1,547 5'UTR variants in IRD genes have been submitted to the ClinVar database thus
409 far (**Table S11**). All variants except 4 have been clinically interpreted. Only 2% (31/1,547) of
410 the variants have been classified as pathogenic or likely pathogenic, of which 32% (10/31) and
411 16% (5/31) were found in the *PAX6* and *NMNAT1* genes, respectively. On the other hand, 34%
412 (527/1,547) of the 5'UTR variants have been classified as benign or likely benign, of which no
413 single gene was found to account for more than 5% of these variants. While 5% (81/1,547) of

414 the variants had conflicting interpretations of pathogenicity, the largest fraction comprising
415 58% (904/1,547) of all variants have been classified as VUS.

416 **Analysis of 5'UTRs in WGS and WES data of two IRD cohorts reveals rare and ultra-rare**
417 **variants predicted to affect 5'UTR function**

418 To systematically assess the contribution of 5'UTR genomic variation to IRDs, we performed a
419 variant analysis within the selected 643 genomic regions in affected individuals from two
420 different IRD sub-cohorts, namely the GE (n=2,397 WGS) and CMGG (n=1,682 WES) cohorts.
421 We identified a total of 2,898 and 381 distinct 5'UTR variants within the GE and CMGG cohorts,
422 respectively. The majority of these variants (2,637/2,898 and 334/381) had a minor allele
423 frequency (MAF) lower than 2% in all populations and a substantial fraction (506/2,898 and
424 92/381) was found to be absent from all reference population public databases. To aid the
425 interpretation of these 5'UTR variants, we classified them into 7 (non-mutually exclusive)
426 categories according to their *in silico* predicted functional consequences (**Figure 1**). A
427 summarized overview of the number of variants that remained after classification and
428 category-specific filtering can be found in **Table 1**. Out of the 1,450 remaining variants
429 (**Dataset S1**), 370 were present in more than one category. Of the remaining variants assigned
430 to a single category, the bulk corresponded to variants overlapping a retinal TSS or an IRES
431 (761/1,450; 221 -TSS-, 488 -IRES-, 52 -TSS & IRES-), followed by variants with a predicted
432 change in secondary structure minimum free energy (204/1,450). When comparing the
433 number of variants in each category between the two cohorts, we observed statistically
434 significant differences in the number of variants overlapping a retinal TSS and/or IRES, for
435 which the proportion of variants was higher for the WGS-based GE cohort compared to the
436 WES-based CMGG cohort (~55% and ~35% respectively, $p < 0.05$). These differences are most
437 likely due to the expanded capture of regions including TSS allowed by the use of WGS in the

438 GE cohort. Additionally, it is noteworthy that for the IRD genes with 5'UTRs harboring IRES
439 (92/378), these elements were found to span on average 61% of the 5'UTR and even its entire
440 length for certain genes (12/92) (**Table S12**).

441 **Table 1. Summarized overview of the number of 5'UTR variants that remained after functional**
442 **classification and filtering.**

	GE cohort	CMGG cohort	Total	%
uAUG gained	30	5	35	2.41
Change in existing uORF	17	1	18	1.24
Alteration of classical or retinal primary Kozak context	16	6	22	1.52
Splicing	29	10	39	2.69
Change in translational efficiency	1	0	1	0.07
Change in secondary structure minimum free energy	194	10	204	14.07
Overlapping a retinal transcription start site or an IRES	692	69	761	52.48
> 1 category	276	94	370	25.52
Total	1255	195	1450

444 site; uORF, upstream open reading frame.

445 **Systematic variant evaluation allows the prioritization of candidate pathogenic 5'UTR**
446 **variants**

447 To enhance the likelihood of identifying potential pathogenic 5'UTR variants, we prioritized
448 the ones with higher predicted impact based on specific criteria for each category (**Figure 1**)
449 and for which the inheritance patterns and reported phenotypes fitted the genes in which the
450 5'UTR variants had been identified. The application of this prioritization procedure is
451 illustrated in **Table S13**. We prioritized 11 candidate pathogenic 5'UTR variants. Of these, 10
452 were found in unsolved cases and 8 have not been reported before. Of note, although initially
453 identified through WGS, 6 of these variants would also be covered by WES. An overview of

454 the genetic, phenotypic, and *in silico* prediction details of these variants is shown in **Table 2**.
455 The pedigrees of these families including variant segregation are shown in **Figure S5**.
456 Four of these variants were found to alter splicing in genes linked to autosomal dominant
457 (*PRPF31*), autosomal recessive (*NMNAT1*) and X-linked (*NDP*) disease. The *NDP*:c.-70G>A and
458 *PRPF31*:c.-9+1G>A variants have recently been reported by Daich Varela *et al.* (2022)⁴⁸. We
459 identified a *de novo* variant (*PRPF31*:c.-9+1G>T) in the same 5'UTR position of *PRPF31* in a
460 sporadic case with rod-cone dystrophy in which bi-allelic *GRM6* variants had been identified,
461 one of them reported as likely benign (**Table S14**). Variants in *GRM6* cause autosomal
462 recessive congenital stationary night blindness⁸⁹, which is different from the clinical diagnosis
463 in this proband. The *NMNAT1*:c.-57G>A variant was found in an individual with macular
464 dystrophy that carries *in trans* an extremely rare missense variant for which *in silico*
465 predictions support a pathogenic effect.
466 Changes in secondary structure were predicted for 4 variants in genes linked to autosomal
467 dominant (*ARL3*, *PAX6*) and autosomal recessive (*MERTK*, *RD3*) disease (**Figure S6**). Given the
468 inheritance pattern and *in silico* predictions, a gain-of-function effect was hypothesized for
469 the *ARL3*:c.-88G>A and *PAX6*:c.-44T>C variants. Both the *MERTK*:c.-125G>A and *RD3*:c.-
470 394G>A variants were identified in homozygous state and found to overlap their respective
471 TSS.
472 The introduction of an uORF was predicted for 2 variants in the *NPHP4* and *RDH12* genes. In
473 contrast to the uORF created by the *RDH12*:c.-123C>T variant, the one introduced by the
474 *NPHP4*:c.-21C>T variant is out-of-frame and overlaps the CDS. Although no segregation could
475 be established for this case with non-syndromic rod-cone dystrophy, an ultra-rare missense
476 *NPHP4* variant with pathogenic *in silico* predictions was identified.

477 Only one variant in a gene linked to dominant disease (*PRPF4*) was predicted to affect the
478 primary Kozak consensus sequence. The *PRPF4*:c.-6C>T variant results in a transition to an
479 infrequent nucleotide at this position within the Kozak consensus sequences derived from the
480 IRD gene isoforms selected in this study (**Figure S7**). This variant was found in a sporadic case
481 with rod-cone dystrophy in which 2 likely pathogenic variants have been identified in the
482 *ITF140* gene (**Table S14**); segregation analysis was not possible to establish the phase of any
483 of these alleles.

484 Four of the variants (*ARL3*:c.-88G>A, *MERTK*:c.-125G>A, *PAX6*:c.-44T>C, *RDH12*:c.-123C>T)
485 were selected for functional validation using diverse multiple experimental approaches.

486 **Downstream functional analyses support the pathogenicity of the *MERTK*:c.-125G>A and**
487 ***RDH12*:c.-123C>T variants**

488 Depending on the tissue-specific gene expression and availability of patient material, we
489 conducted either *in vitro* evaluation in ARPE-19 cells (dual luciferase assays or
490 overexpression), or mRNA expression analysis in patient-derived lymphocyte cultures (**Figure**
491 **4A**). The *RDH12*:c.-123C>T and *MERTK*:c.-125G>A variants were found to result in a significant
492 decrease in luciferase activity (**Figure 4B**). To further elucidate the underlying mechanism,
493 *Renilla* mRNA expression analysis was performed. Relative *Renilla* luciferase mRNA levels
494 remain unchanged for *RDH12*:c.-123C>T, whereas a significant decrease was observed for
495 *MERTK*:c.-125G>A (**Figure 4C**), hence suggesting a translational and a transcriptional effect for
496 these variants, respectively.

497 Taking advantage of the expression of *ARL3* in accessible tissues, we performed qPCR-based
498 quantification of *ARL3* mRNA abundance in lymphocyte cDNA from the two affected siblings
499 in whom we identified the *ARL3*:c.-88G>A variant and five healthy controls. No significant
500 differences were observed in *ARL3* mRNA abundance between the affected carriers and

501 controls (**Figure 4D**). Interestingly, *ARL3* expression levels were slightly higher in the patient
502 samples derived from the lymphocyte cultures treated with puromycin, a translation inhibitor
503 used to suppress nonsense-mediated mRNA decay, compared to the corresponding untreated
504 samples and controls. Therefore, although the *ARL3*:c.-88G>A variant was not predicted to
505 affect splicing, we also performed Sanger sequencing on the cDNA derived from the
506 puromycin-treated and untreated patient lymphocyte cultures. Neither splicing defects nor
507 allele-specific expression were observed (*data not shown*).

508 In view of the negative results obtained for the *PAX6*:c.-44T>C and *ARL3*:c.-88G>A variants,
509 the phenotypes of patients F9 and F10 were re-evaluated. Neither anterior segment
510 abnormalities nor other clinical presentations compatible with a *PAX6*-related disease were
511 observed in patient F9 or her affected relatives. Regarding F10, re-evaluation of one of the
512 affected siblings revealed an acquired vascular ocular condition instead of an IRD.

513 **The *RDH12*:c.-123C>T 5'UTR variant is found always *in cis* with the p.Arg234His hypomorphic**
514 **allele and results in reduced *RDH12* protein levels**

515 We identified the *RDH12*:c.-123C>T variant in one solved case from the GE cohort
516 characterized by bi-allelic *RDH12* coding variants (c.[701G>A];[c.735_743del], p.[Arg234His];
517 [Cys245_Leu247del]). The 5'UTR variant, reported as VUS in ClinVar, was found in *cis* with the
518 p.Arg234His allele. Further evaluation of this 5'UTR variant in 10 additional *RDH12* bi-allelic
519 patients from 8 families carrying the p.Arg234His variant revealed that the c.-123C>T and
520 p.Arg234His variants always form a complex allele (**Table S15**). This was also shown for 7
521 carriers of the p.Arg234His variant affected by other pathologies (*data not shown*).

522 Here, we report the first patient who is homozygous for the *RDH12*: c.[-123C>T];[701G>A]
523 complex allele (**Table S15**). Compared to other patients carrying the 5'UTR variant *in trans*

524 with a null *RDH12* allele⁹⁰, patient F21 presents with a milder phenotype (mild decreased
525 acuity (20/25 OD and OS) in fourth decade of life, foveal sparing maculopathy with a
526 circumscribed area of atrophy within the vascular arcades, without a nasal component.

527 The c.-123C>T variant is predicted to introduce an uAUG into a strong Kozak consensus
528 sequence that is in-frame with a stop codon located 75 nucleotides downstream in the 5'UTR.
529 In view of the results obtained in the luciferase assays and the predicted uORF-introducing
530 effect of the 5'UTR variant, we further inspected the potentially exclusive effect at the
531 translational level by assessing *RDH12* mRNA abundance and protein levels in an
532 overexpression setting. Although we could not confirm translation of the 25-amino-acid-long
533 peptide predicted to be encoded by the uORF by co-immunoprecipitation (*data not shown*),
534 we observed unaltered mRNA but significantly ($p<0.05$) reduced *RDH12* protein levels,
535 thereby providing further evidence for a post-transcriptional or translational effect (**Figure 4E-**
536 **F**) which was already suggested by the mRNA evaluation in the luciferase assays.

537 **Discussion**

538 Given the emerging role of non-coding variation underlying IRDs^{45,48,52–55} and the essential
539 regulatory function of 5'UTRs^{2,6}, we set out to evaluate their contribution to this
540 heterogeneous group of disorders by analyzing, systematically annotating, filtering and
541 prioritizing 5'UTR variants in two large IRD cohorts in combination with different experimental
542 approaches for functional validation.

543 Thus far, only a few studies have implicated 5'UTR variation in the molecular pathogenesis of
544 IRD cases^{48,53,54}. Our retrospective analysis of 5'UTR variants in IRD genes listed in the ClinVar
545 database⁶⁶ revealed that as many as 58% of all variants have been classified as VUS. A large
546 fraction of the underrepresentation of (likely) pathogenic 5'UTR variants in clinical databases

547 can be explained by their exclusion from downstream tiering pipelines, which prioritize
548 variants with protein-altering consequences and hence neglect the potential impact of 5'UTR
549 variants⁹¹. Furthermore, the identification of these variants is not always feasible by means of
550 commercial exome enrichment platforms, in particular when variants are found within 5'UTR
551 exons that are not part of or proximal to the first protein-coding exon¹⁹. Here, we show that
552 the enriched 5'UTR fraction is highly dependent on the WES capture kit used, and ranges from
553 7% to 39%. Overall, as previous studies have also argued⁹²⁻⁹⁴, our analysis underscores the
554 diagnostic value of re-analyzing exome data, in which causative variants might already be
555 present but previously disregarded.

556 Furthermore, the identification of the genetic defects underlying IRDs is greatly impacted by
557 the inherent complexity of the retinal transcriptional landscape. Variants in retina-enriched
558 isoforms and tissue-specific mis-splicing have been shown to be important molecular
559 mechanisms underpinning disease pathogenesis and phenotypic heterogeneity⁹⁵⁻⁹⁹. As gene
560 isoforms can display differential 5'UTRs that can result in differential translational
561 efficiencies¹⁰⁰, we performed a transcript-level re-analysis of retinal expression data to obtain
562 a relevant selection of 5'UTRs of IRD genes for downstream variant analysis. We identified 76
563 IRD genes with alternative isoforms exhibiting retinal expression levels higher than their
564 respective canonical isoforms, of which 20 displayed a fully distinct 5'UTR. This analysis also
565 found the recently identified photoreceptor-specific non-canonical *CRB1* isoform, which bears
566 a unique 5'UTR exon¹⁰¹. Similarly, we confirmed the retinal enrichment of an alternative
567 *RIMS2* isoform containing an unconventional 5'UTR exon, which has been shown to be
568 photoreceptor-specific and functionally conserved in mouse (Del Pozo-Valero *et al.*,
569 *unpublished data*). By revealing that a significant fraction of IRD genes express alternative

570 retinal isoforms, our analysis highlights the importance of isoform-aware variant annotation
571 for adequate interpretation.

572 To aid the assessment of 5'UTR variant pathogenicity, *in silico* tools have recently been
573 developed, with an emphasis put on uORF-perturbing variants^{20,26}. A systematic
574 characterization of this class of 5'UTR variants showed that they are subject to strong negative
575 selection, which could even be equivalent to that observed against missense variants¹¹.
576 However, thus far, these tools do not provide comprehensive annotations of all possible
577 effects 5'UTR variants can exert⁸. Here, we designed an integrative annotation of 5'UTR-
578 informative features and built a prioritization strategy combining family and phenotypic data
579 to increase the probability of identifying potential pathogenic 5'UTR variants. Although we
580 performed these analyses in IRD cohorts, the features evaluated, and the methods presented
581 in this study can be extrapolated and applied in any setting involving clinical interpretation of
582 5'UTR variation.

583 We prioritized 11 candidate pathogenic 5'UTR variants. The great majority of these variants
584 (8/11) have not been reported before, most likely due to their exclusion from routine
585 prioritization pipelines and subsequent clinical interpretation⁹¹. These 11 variants were
586 assigned to 5 of the 7 categories we defined to classify their potential functional
587 consequences, thus reflecting the diversity in predicted functional effect. Of note, the majority
588 (4/11) was predicted to have an effect on splicing which, in line with our analysis revealing
589 that almost one third of all IRD genes have their 5'UTRs spliced, supports that these regions
590 are also susceptible to disease-causing splicing defects. Notably, we also provided a set of
591 filtered annotated 5'UTR variants with *in silico* predictions pointing to a pathogenic effect that
592 were not prioritized as candidates due to inconsistent genotypes or phenotypes in the patients
593 evaluated. Therefore, we cannot dismiss the possibility that these variants can have a

594 pathogenic effect when present in the right context, e.g. *in trans* with a second pathogenic
595 allele in a gene linked to recessive disease.

596 Given the particular importance of providing functional evidence to support the pathogenicity
597 of variants located within non-coding regions, we evaluated the predicted functional
598 consequence of 4 candidate variants. Despite the extreme rarity and disease co-segregation
599 of the *PAX6*:c.-44C>T variant, both the lack of functional evidence and the unusual phenotype
600 established upon clinical re-evaluation indicate that this variant is not explaining the
601 phenotype. Likewise, we could not confirm the predicted effect of the *ARL3*:c.-88G>A variant
602 using accessible patient-derived material. The sibling of the proband was eventually
603 considered not affected by an IRD, indicating that the variant is either not causative,
604 incompletely penetrant, or simply a recessive allele. Interestingly, a phenotype similar to that
605 of the proband has been associated with a pathogenic variant in this gene¹⁰², which could
606 suggest that this variant exerts a retina-specific effect that cannot be evaluated with the
607 current experimental setting. Nevertheless, it is important to note that in this case both
608 siblings have been studied by WES, but were not tested for known deep-intronic and structural
609 variants. Before proceeding with further functional characterization of the *ARL3*:c.-88G>A
610 variant, WGS should thus be performed to confirm or rule out such variants. Altogether, these
611 results highlight the need and potential limitations of experimental assays to validate the
612 functionality of non-coding variants.

613 We could provide a novel molecular diagnosis in a patient with severe early-onset retinal
614 dystrophy that remained unsolved after WGS screening. This individual was found to be a
615 homozygous carrier for the extremely rare c.-125G>A variant in *MERTK*, overlapping its
616 transcription start site, for which our *in silico* predictions pointed to an effect at the
617 transcriptional level. A drastic reduction of luciferase activity accompanied by decreased

618 relative *Renilla* luciferase mRNA levels confirmed the hypothesized transcriptional effect of
619 the variant, which is consistent with a loss of function of *MERTK*. To our knowledge, this is the
620 first reported disease-causing 5'UTR variant in *MERTK*.

621 One of the candidate pathogenic 5'UTR variants was found in a case solved with bi-allelic
622 *RDH12* coding variants, namely the p.Arg234His hypomorphic missense^{90,103,104} and the
623 p.Cys245_Leu247del in-frame variants. The identified c.-123C>T 5'UTR variant was found *in*
624 *cis* with p.Arg234His, both in this case as well as in 10 additional *RDH12* bi-allelic patients
625 screened for this 5'UTR variant, with one of them being homozygous for this complex allele.
626 The pathogenicity of p.Arg234His has been questioned in view of functional assays revealing
627 *RDH12* protein levels and catalytic activity comparable to the wild-type or polymorphic alleles,
628 respectively¹⁰⁵. We therefore hypothesized a pathogenic effect exerted by the *RDH12*:c.-
629 123C>T variant as part of this complex allele. This 5'UTR variant was predicted to introduce an
630 upstream start codon (uAUG) into a strong Kozak consensus, thereby creating an uORF. Given
631 that ribosomes would first encounter and start translating from this gained uAUG, we
632 hypothesized that this variant would decrease normal *RDH12* translation and thus result in
633 lower protein levels. Furthermore, this variant has been argued to affect the function of an
634 alternative promoter of *RDH12* based on the observed decreased activity in a luciferase
635 reporter assay⁵². Importantly, this experimental setup did not include comparison between
636 mRNA levels and luciferase protein activity and was therefore unable to pinpoint at which
637 level the effect occurs. Here, using a dual luciferase assay with the 5'UTR instead of the
638 genomic sequence, followed by downstream evaluation at both the mRNA and protein level,
639 we confirmed the hypothesized uORF-mediated effect. We tested this hypothesis further
640 using an overexpression setting and demonstrated unaltered mRNA but significantly reduced
641 *RDH12* protein levels, hence confirming the translational effect of *RDH12*:c.-123C>T variant.

642 Although we could not obtain experimental evidence supporting the translation of the uORF-
643 encoded peptide, which might suggest its instability, we cannot rule out alternative
644 mechanisms such as ribosome stalling⁹. However, further studies are needed to confirm this
645 hypothesis. Overall, our results indicate that not p.Arg234His alone, but rather the
646 combination of p.Arg234His and c.-123C>T, or even c.-123C>T by itself, is disease-causing
647 **(Figure 5)**.

648 **Conclusions**

649 5'UTRs are essential modulators of post-transcriptional and translational control. Even though
650 they can be captured by WES to a large extent, variants within these regions are typically
651 overlooked in both research and routine clinical settings, mainly due to their challenging
652 interpretation. In this study, we developed a systematic strategy to comprehensively annotate
653 and prioritize 5'UTR variants in IRD genes. This strategy combined with functional studies
654 allowed us to pinpoint 5'UTR variants providing either novel molecular diagnoses or the full
655 picture explaining the pathogenicity of previously reported hypomorphic variants. Overall, in
656 this study we highlight the importance of multi-layered annotation and validation of non-
657 coding variation potentially underlying disease and provide a 5'UTR interpretation approach
658 that could be extrapolated to other rare diseases.

659

661

662

663 **Abbreviations**

- 664 5'UTR: 5' untranslated region
- 665 AD: Autosomal dominant
- 666 AR: Autosomal recessive
- 667 CAGE-seq: Cap analysis gene expression sequencing
- 668 CMGG: Center for Medical Genetics Ghent
- 669 CDS: Coding sequence
- 670 DMEM: Dulbecco's minimal essential medium
- 671 ERDC: European Retinal Disease Consortium
- 672 FC: Fold change
- 673 GE: Genomics England
- 674 IRD: Inherited retinal disease
- 675 IRES : Internal ribosomal entry sites
- 676 MAF: Minor allele frequency
- 677 OD/OS: *Oculus dexter/sinister* (right/left eye)
- 678 qPCR: Quantitative polymerase chain reaction
- 679 SNV: Single-nucleotide variant
- 680 SV: Structural variant
- 681 TSS : Transcription start site
- 682 TPM: Transcripts per million
- 683 TE: Translational efficiency
- 684 uORF: Upstream open reading frame
- 685 VUS: Variant of uncertain significance
- 686 WES/WGS: Whole exome/genome sequencing

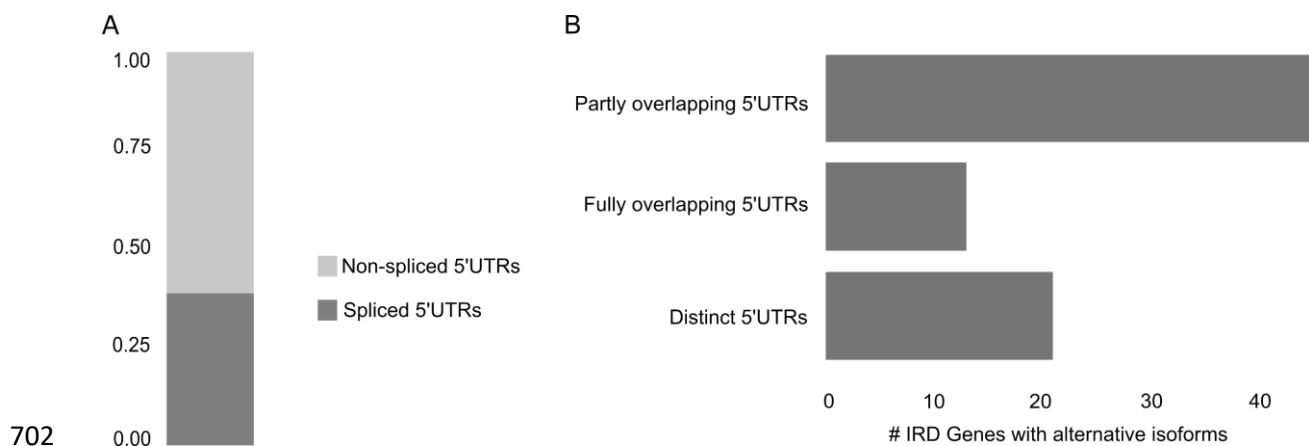

687

688 **Figure 1. Functional annotation of 5'UTR variants, filtering, and prioritization strategy followed in**
 689 **this study.** A combination of *in silico* tools (see *Methods*) was used to annotate 5'UTR variants, which
 690 were then classified into 7 functional categories. For each of these categories, specific criteria were
 691 established for prioritizing variants with a more likely functional impact (*bottom*). Only variants with a
 692 minor allele frequency (MAF) $< 2\%$ were further studied. The following information was then reviewed:
 693 inheritance pattern of the family (AR including sporadic cases; AD; XL) and clinical features. For the
 694 selection of candidate variants, both had to be in agreement with the reported mode of inheritance
 695 and phenotype associated with the gene in which the 5'UTR variant was found. Abbreviations: AD:
 696 autosomal dominant; AR: autosomal recessive; FC: fold change; IRES: internal ribosomal entry site; TE:
 697 translational efficiency; TSS: transcription start site; uAUG: upstream AUG; uORF: upstream open
 698 reading frame.

704 isoforms based on the structure of their 5'UTRs. **(B)** Classification of IRD genes with a retina-enriched
705 isoform differing to the canonical one based on the comparison of their respective 5'UTRs.
706

707
708 **Figure 3. Evaluation of 5'UTR capture by whole-exome sequencing (WES). (A)** Boxplots showing the
709 capture performance (*x-axis*) of commonly used commercial exome capture designs on the selected
710 5'UTRs. The kits that were mostly used for the generation of our in-house WES data are highlighted in
711 *darker gray*. **(B)** Histogram representing the portions of 5'UTRs (*y-axis*) of the selected IRD genes which
712 are captured by the SureSelect Human All Exon V6 kit (Agilent Technologies) considering a *strict* or a
713 *padded* design (*see Methods*).

714

715 **Figure 4. Functional evaluation of candidate pathogenic 5'UTR variants in the ARL3, MERTK, PAX6,**

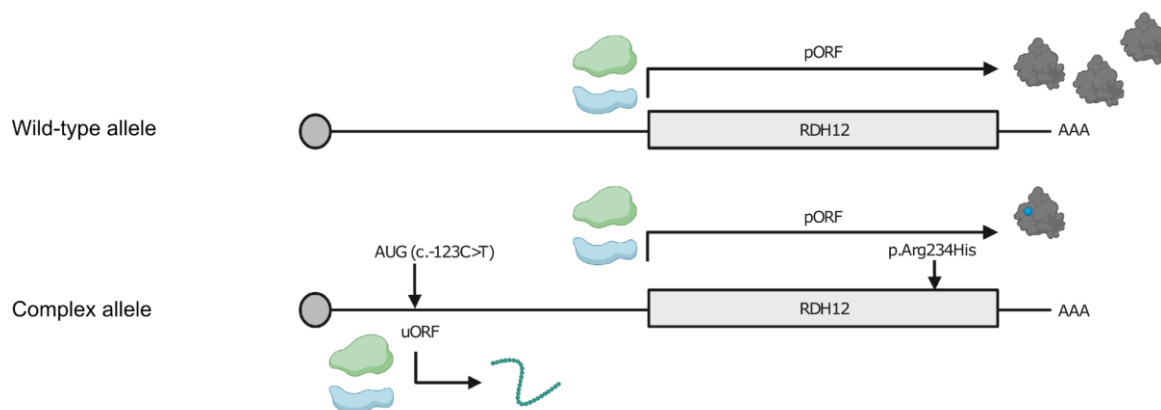

716 **and RDH12 genes. (A)** Various approaches were used for functionally evaluating candidate variants,

717 including *in vitro* studies (dual luciferase reporter assays and overexpression) and experiments with

718 clinically-accessible tissues (expression analysis in patient-derived lymphocytes). **(B)** Results from the

719 luciferase assays for the MERTK:c.-125G>A, PAX6:c.-44C>T, and RDH12:c.-123C>T variants. The bar

720 plot shows, for each variant, the fold change (FC) of the luciferase reporter level relative to the level
721 of their corresponding wild-type (WT) construct luciferase vector (FC= 1). The *RDH12*:c.-123C>T and
722 *MERTK*: c.-125G>A variants resulted in significant ($p<0.001$) decrease in luciferase activity (~92% and
723 ~99%, respectively). **(C)** Relative *Renilla* luciferase mRNA levels were significantly decreased (~42%,
724 $p<0.01$) for the *MERTK*:c.-125G>A variant while they remain the same for the *RDH12*:c.-123C>T variant
725 when normalized to mRNA of *Firefly* luciferase and compared to their corresponding wild-type (WT)
726 construct luciferase vectors. **(D)** qPCR quantification of *ARL3* mRNA abundance in lymphocyte cDNA of
727 two affected siblings carrying the *ARL3*:c.-88G>A novel variant and five healthy controls. No significant
728 differences were observed in *ARL3* mRNA abundance between the affected carriers and controls. **(E-**
729 **F)** Using an overexpression setting, the *RDH12*:c.-123C>T variant was shown to result in **(E)** unaltered
730 mRNA levels but **(F)** significantly reduced (~73%, $p<0.01$) RDH12 protein levels.

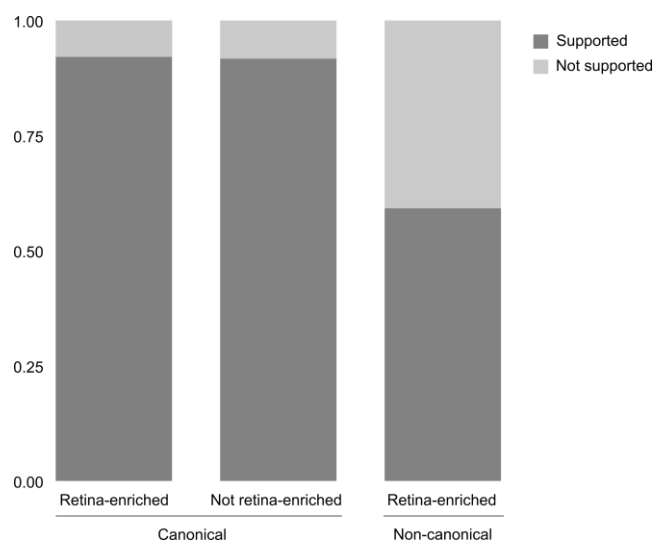

731
732 **Figure 5. Proposed pathogenic mechanism of the *RDH12*: c.-123C>T];[701G>A] complex allele.**
733 Graphical representation of the *RDH12* wild-type allele (*top*) and the *RDH12* complex allele harboring
734 the c.701G>A (p.Arg234His) and the c.-123C>T variants (*bottom*). The 5'UTR variant introduces an
735 upstream start codon into a strong Kozak sequence which can be recognized by ribosomes. Either
736 initiation or active translation of the introduced upstream open reading frame (uORF) results in lower
737 translational efficiency of the primary open reading frame (pORF). As a result, there is a decreased
738 level of RDH12 protein with the arginine-to-histidine amino acid substitution at position 734 (*blue*
739 *point*).

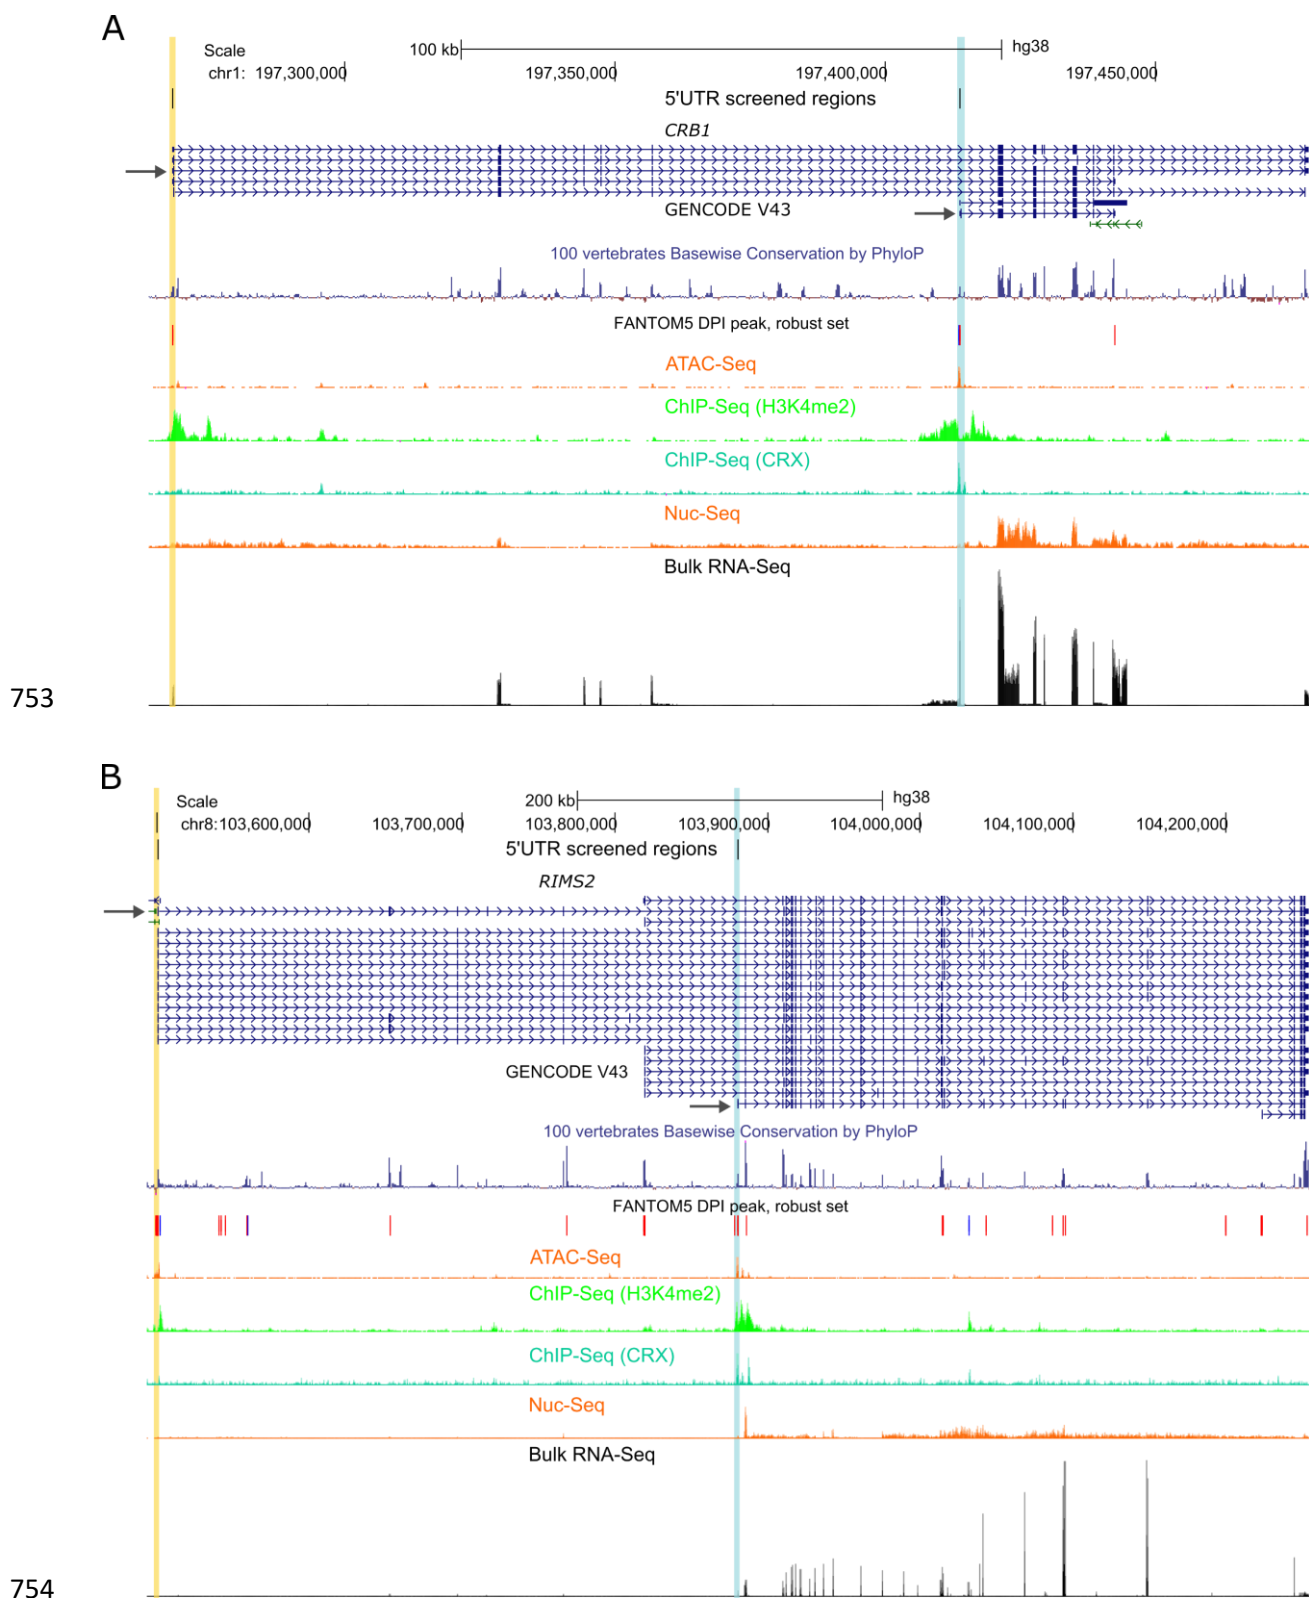

740

741 **Figure S1. Schematic overview of constructs used for functional studies.** (A) The wild-type (WT)
 742 5'UTRs of the *MERTK*, *PAX6*, and *RDH12* genes were cloned in-frame into a psiCHECK™-2 dual luciferase
 743 vector (Promega), containing the *Renilla* and *Firefly* luciferase reporter genes under the regulation of
 744 the SV40 and HSV-TK promoters, respectively. (B). Depiction of the overexpression RDH12 construct
 745 comprising the 5'UTR and primary open reading frame (pORF) of *RDH12*, for which Myc and FLAG in-
 746 frame tags were included downstream, respectively. This fragment was cloned into a pcDNA™3.1⁽⁺⁾
 747 (Invitrogen) vector downstream its T7 promoter. For all constructs, 5'UTRs variants were created by
 748 site-directed mutagenesis to obtain mutant (MT) constructs with the variants of interest.

749

750 **Figure S2. Assessment of transcription start site (TSS) confidence by CAGE-seq in retina.**
 751 Representation of the proportion of IRD gene isoforms based on the support of their annotated TSS
 752 provided by CAGE-seq data derived from adult and fetal retina.

755 **Figure S3. Retina-enriched non-canonical isoforms of the *CRB1* and *RIMS2* genes.** The shorter
756 alternative isoforms of (A) *CRB1* (ENST00000681519) and (B) *RIMS2* (ENST00000436393) contain
757 5'UTRs which are completely distinct to those of their respective canonical isoforms

758 (ENST00000367400.8 and ENST00000696799.1, respectively). The transcription start sites (supported
759 by CAGE-seq) of each canonical and non-canonical isoform (indicated by arrows) are highlighted in
760 *yellow* and *blue*, respectively. Active retinal transcription is supported by bulk RNA-seq and Nuc-seq
761 derived from human retina. The enrichment in retina of these isoforms is further supported by
762 signatures of open chromatin, H3K4me2, and binding of the retina-specific transcription factor CRX
763 (datasets used are listed in **Table S2**).

827 Díaz; IOB: Institute of Molecular and Clinical Ophthalmology Basel; MEH: Moorfields Eye
828 Hospital.

829 **Additional file 2 - Dataset S1.** Annotation of the 1,450 5'UTRs variants that remained after
830 functional classification and filtering. For each cohort (GE or CMGG) there is one tab per
831 functional category.

832

833 **Declarations**

834 **Ethics approval and consent to participate**

835 The 100,000 Genomes Project Protocol has ethical approval from the HRA Committee East of
836 England – Cambridge South (REC Ref 14/EE/1112). This study was registered with Genomics
837 England within the *Hearing and sight domain* under Research Registry Projects 465. This study
838 was approved by the ethics committee for Ghent University Hospital (B6702021000312) and
839 performed in accordance with the tenets of the Helsinki Declaration and subsequent reviews.

840 **Consent for publication**

841 Not applicable. We present only de-identified data.

842 **Availability of data and materials**

843 The data that support the findings of this study are available within the Genomics England
844 (protected) Research Environment but restrictions apply to the availability of these data, as
845 access to the Research Environment is limited to protect the privacy and confidentiality of
846 participants. Likewise, healthcare and genomic data derived from individuals included in the
847 Center for Medical Genetics Ghent (CMGG) cohort are not publicly available to comply with
848 the consent given by those participants. De-identified data as well as analysis scripts are
849 available from the authors upon reasonable request. Extended data generated in this study
850 are available in the supplementary materials.

851 **Competing interests**

852 The authors declare that they have no competing interests.

853 **Funding**

854 This work was supported by the Ghent University Special Research Fund (BOF20/GOA/023;
855 BOF/STA/201909/016) (EDB, BPL, FCP); H2020 Marie Skłodowska-Curie Innovative Training
856 Networks (ITN) StarT (grant No. 813490) (ADR, EDB, FC); Ghent University Hospital under the

857 NucleUZ Grant (EDB, FC); Foundation Fighting Blindness (TA-GT-0621-0810-UGENT) (FCP);
